ESAs have improved hemoglobin levels in patients with ACI, reducing the necessity for RBC transfusion, especially with endogenous Epo levels of <500 IU/L. The addition of typically parenteral administration of iron can be considered in ACI patients who are unresponsive to ESA alone. ESAs lead to increased hemoglobin levels in patients with a variety of non-hematologic malignancies (with or without chemotherapy), including squamous cell cancer, breast cancer, and colon cancer. However, despite the benefits of decreasing RBC transfusion requirements and improved quality of life, ESAs (both short- or long-acting forms) in patients with cancer and kidney disease increase the risk of stroke and thromboembolic events.[26] Studies have also indicated that critically ill patients and those with cancer undergoing chemotherapy may have an increased rate of thrombosis and overall death when treated with ESAs, particularly in patients with post-treatment hemoglobin >10–11 g/dL. In a large study, normalizing hemoglobin (12.0–15.0 g/dL) in ESA-treated ESRD patients with cardiac disease led to an increased number of cardiac events and deaths compared to partial hemoglobin normalization (10.5–11.5 g/dL). Although pretreatment hemoglobin levels in patients with breast cancer or head and neck cancer have been demonstrated repeatedly to predict good response to chemotherapy and radiation, patients treated with ESAs risk increased disease progression and decreased survival relative to placebo-treated patients. Based on these and other studies, the US Food and Drug Administration has warned that ESAs should be given only in the lowest possible doses necessary to avoid RBC transfusions. More recently, consensus recommendations for patients with cancer support the use of ESAs only in those receiving chemotherapy for palliative, rather than curative, intent. Thus, ESAs should be used sparingly, if at all, with active malignancy.

In the appropriate nonmalignant setting of symptomatic ACI, weekly subcutaneous ESA administration can be initiated. If a hemoglobin response is seen, the dose can be decreased and the interval prolonged to titrate the hemoglobin to a minimal asymptomatic level. Follow-up and dose titration are essential to minimize expense, injections, and potential deleterious effects from over- or under-treatment. The ESA response may take 4–8 weeks and should be monitored for objective symptomatic improvement (e.g., exercise tolerance). Approximately 35%–40% of patients demonstrate primary resistance. Predictors of ESA resistance include iron or vitamin deficiency, recent RBC transfusion requirement, and higher endogenous Epo levels before initiation of therapy. If, after 2 weeks of treatment, the serum Epo level is >100 mU/mL and the hemoglobin concentration has not increased by ≥0.5 g/dL, or if the serum ferritin level remains >400 ng/mL, a response is unlikely.[27] In a multivariate analysis of 80 patients with ACI in the context of cancer, only the hemoglobin, serum Epo, and serum ferritin levels, but not disease status, bone marrow involvement, or treatment status, were independent predictors of response to ESAs.

An important factor limiting response to ESAs is functional iron deficiency. Correction of functional iron deficiency with parenteral iron supplementation can decrease the required dosage while improving the effect of ESAs. Parenteral iron improves ESA responses and is cost-effective in ESRD patients, even those with elevated ferritin levels; however, the widespread applicability of this approach, and its long-term effects, are not known.

in development target either the hepcidin molecule or its regulators (e.g., BMP) in the hope that the potential therapeutic efficacy of hepcidin antagonists may extend to even mild anemias.

Via the Inflammatory Signal

Several diseases in the ACI category (e.g., Castleman disease and RA) have benefited from clinical trials with hepcidin-lowering agents (Table 38.2). Therapeutic monoclonal antibodies against IL-6 receptor (tocilizumab), IL-6 (siltuximab), and TNF-α (golimumab or infliximab) resulted in decreased hepcidin and improved anemia. In addition, downstream inhibition of STAT3 signaling (e.g., curcumin, AG490, and PpYLKTK) has demonstrated effectiveness in decreasing hepcidin in vitro and in pre-clinical studies in vivo. They are, however, unlikely to come to market as a consequence of their non-specific effects (all), competing iron-chelating properties (curcumin), and suboptimal pharmacokinetics (AG490 and PpYLKTK).

Via the Iron Signal

Heparin, a glycosaminoglycan and frequently used agent in the treatment and prophylaxis of blood clots, has a high affinity for BMPs. Thus, heparin inhibits hepcidin expression by binding to and sequestering BMPs.[28] Furthermore, heparins without anticoagulating effects have been developed, demonstrating reversal of anemia in mouse models of ACI and are specifically able to block hepcidin in vitro and in pre-clinical studies in vivo. These agents are poised for randomized clinical trials. Hemojuvulin (HJV) is a BMP coreceptor, enhancing hepcidin expression. Soluble HJV, resulting

TABLE 38.1 **Currently Available Therapeutic Options for Management of Anemia of Chronic Inflammation**

	Benefit	Risk
Treat underlying illness	• Most widely accepted as effective • Most disease-specific therapy	• Typical underlying illness often long term • 30% of ACI patients without identifiable illness
RBC transfusion	• Rapid increase in hemoglobin	• Requires a clinical setting for administration • Complications: hemolytic reactions, allo-immunization, infection, iron overload with repeat administration[a]
ESA	• Amenable to self-administration	• Relatively contraindicated in patients with cancer
Parenteral iron	• Multiple options for formulation available	• Requires a clinical setting for administration • Infusion reactions, albeit mild (e.g., self-limiting "Fishbein" reaction), may occur with all typically used formulations (unlike anaphylaxis with previously used high molecular weight iron dextran) • Does not benefit patients without "iron-restricted erythropoiesis" (see Fig. 38.3)

ACI, Anemia of chronic inflammation; *ESA*, erythropoietin stimulating agents; *RBC*, red blood cell.
[a] See Chapter 37 for a full list of complications of RBC transfusion.

from cleavage of cellular HJV, competes for binding of BMP to BMP receptor. Administration of either neutralizing anti-HJV antibodies (AbbVie Pharmaceuticals) or sHJV fused with IgG Fc fragment result in hepcidin suppression and correct anemia in murine ACI models.[29,30] Clinical studies using such agents in renal failure patients are underway.

Antibodies and small molecule inhibitors of BMP/SMAD have also demonstrated pre-clinical efficacy in decreasing hepcidin expression. For example, anti-BMP6 antibodies, dorsomorphin, an inhibitor of BMP/SMAD signaling, and dorsomorphin derivatives, e.g., LDN-193189, reduce hepcidin expression and increase serum iron concentration in mice. However, because dorsomorphin and its derivatives do not specifically target BMP/SMAD signaling to hepcidin, they are considered suboptimal candidates for therapeutic development. TP-0184 (Toledo Pharmaceuticals) and momelotinib (Gilead) are specific ALK2 inhibitors undergoing clinical trials in solid tumors and myelofibrosis, respectively. TP-0184 has recently been shown to suppress hepcidin in mouse models of ACI and cancer,[31] but further studies are required to evaluate its full translational potential in ACI.

Via Erythropoietic Signal

Novel hypoxia inducible factor (HIF) stabilizers provide promise in the treatment of ACI, enabling hepcidin blockade mediated via erythropoiesis, simultaneously stimulating erythropoiesis and iron availability. For example, propyl hydroxylase domain-2 (PDH2) inhibitors stabilize HIF-1 and HIF-2, stimulating endogenous Epo production to suppress hepcidin and enable greater iron availability for erythropoiesis.[32–34] In light of the recent discovery of ERFE and its negative regulation of hepcidin, modulation of this pathway is a clear area for future investigation.

Direct Hepcidin Inhibition

Direct hepcidin inhibitors, e.g., hepcidin neutralizing antibodies, have demonstrated efficacy in increasing iron availability for erythropoiesis, reversing anemia, and increasing responsiveness to ESAs in mouse models of ACI and in monkeys. LY2787106, a monoclonal anti-hepcidin antibody (Eli Lily), has recently demonstrated high tolerability, transient iron mobilization, and increased reticulocytosis in a Phase I study of cancer-related anemia patients.[35] PRS-080, a PEGylated anticalin with specific hepcidin binding and neutralizing capacity (Pieris Pharmaceuticals), demonstrated suppression of hepcidin activity in vitro and in mice[36] with decreased hepcidin and transiently increased transferrin saturation at doses above 0.4 mg/kg in a Phase I study in healthy volunteers,[37] warranting further investigations in anemic patients. Lastly, NOX-H94, a spiegelmer (PEGylated non-natural occurring mirror-image L-RNA aptamer) hepcidin antagonist (NOXXON Pharma AG), specifically binds hepcidin with high affinity. NOX-H94 improved ACI in monkeys and prevented hypoferremia in LPS-injected humans volunteers.[38] As a consequence, additional clinical trials in renal insufficiency, ACI, and cancer-related anemia are underway.

CONCLUSION

Anemia is a common consequence of many chronic inflammatory, infectious, and malignant conditions; these are characterized by disturbances in iron metabolism but are often multifactorial. Inflammatory cytokines are the most important causative factors in ACI. The challenges in ACI management are a consequence of (1) inadequate easy to use and standardized diagnostic tools, (2) incomplete appreciation of variability in therapeutic targets for hemoglobin, (3) insufficient guidelines to estimate the degree of functional iron deficit, and (4) incomplete understanding of how to tailor therapy with parenteral iron, ESAs, and RBC transfusion for individual patients. Cytokines such as IFN and TNF have wide-ranging effects, including both direct and indirect inhibition of erythropoiesis and on RBC life span in circulation. Direct inhibition of erythropoiesis is mediated by both a relative decrease in Epo as well as a decrease in iron available for hemoglobin synthesis. Anemia, iron deficiency, and hepcidin may also have independent antimicrobial and antitumor effects to be evaluated in the future. Furthermore, our recently enhanced understanding of the complexity of regulation of iron metabolism and crosstalk with erythropoiesis is starting to bear fruit with novel diagnostic contributions and therapeutics aiming to modulate hepcidin and increase iron availability for erythropoiesis being explored from multiple directions. Different therapeutic strategies for managing ACI associated with different underlying diseases may increase with the potential of hepcidin-targeted therapeutics to enable a greater degree of physiological self-regulation, preventing inadequate or excessing therapy in individual patients. With many novel therapeutic approaches already validated in pre-clinical and clinical settings and some currently being further explored in randomized clinical trials, ACI management is poised to benefit from our extensive additional knowledge regarding iron metabolism and its regulation in physiological and pathological conditions.

TABLE 38.2 Novel Hepcidin Suppressing Agents as Potential Therapy for Anemia of Chronic Inflammation

Mechanism	Pathway	Agent (Company)	Stage of Development
Suppressing inflammatory cytokines and inflammation-mediated signaling	Anti-IL-6 receptor antibody	Tocilizumab (Genentech)	FDA approved 2010; available therapy for multiple autoimmune diseases
	Anti-IL-6 antibody	Siltuximab (Janssen)	FDA approved 2014; available therapy for multicentric Castleman disease
	Anti-TNF-α antibody	Golimumab (Janssen) or infliximab (Janssen)	FDA approved 2013; available therapy for multiple autoimmune diseases
	STAT3 inhibitor	Curcumin, AG490, PpYLKTK	Not proceeding further
Suppressing iron-mediated signaling	BMP sequestration	Heparins (with or without anticoagulating effect) Anti-BMP6 antibody, dorsomorphin and derivatives, e.g., LDN- 193189	FDA approved 1939; available for anticoagulation Phase II, anemia in CKD (no further development)
	sHJV sequestration	Anti-HJV antibody (Abbvie Pharmaceuticals) sHJV-IgG Fc fusion (FerruMax Pharmaceuticals)	Phase II, anemia in CKD (no further development)
	BMP/SMAD inhibitor	ALK2 inhibitors momelotinib (Gilead) and TP-0184 (Toledo Pharmaceuticals)	Phase III, myelofibrosis (FDA fast track status); Phase I, solid tumors
Erythropoiesis- mediated signaling	HIF stabilizer	PHD inhibitor (multiple agents, e.g., roxadustat, daprodustat, vadadustat)	Phase III, anemia in CKD (pending FDA approval only for roxadustat)
Direct hepcidin inhibition	Anti-hepcidin antibody	LY2787106 (Eli Lily)	Phase I, anemia of cancer; Phase II, anemia in CKD (no further development)
	PEGylated anticalin	PRS-080 (Pieris Pharmaceuticals)	Phase IIa, anemia in CKD (completed 2019)
	Spiegelmer, PEGylated non-natural occurring L-RNA-aptamer	NOX-H94 (Noxxon Pharma AG)	Phase IIa, anemia in cancer (no further development)

CHAPTER 39

HEME BIOSYNTHESIS AND ITS DISORDERS: PORPHYRIAS AND SIDEROBLASTIC ANEMIAS

Stephen J. Fuller and James S. Wiley

The porphyrias and the sideroblastic anemias are metabolic disorders that involve defects in heme biosynthesis. Most forms of porphyria are inherited in a Mendelian autosomal dominant pattern, but some types are recessive, and others are acquired through exposure to porphyrinogenic drugs and chemicals. A linked group of diseases, the porphyrinurias, are not porphyrias but have in common alterations of heme biosynthesis following exposure to various toxins.[1] Porphyrins are tetrapyrroles, which are ubiquitous in nature and exhibit characteristic red fluorescence on exposure to ultraviolet light. The iron-porphyrin complex, called *heme*, is central to all biologic oxidation reactions. In plants, the porphyrin molecule is combined with magnesium to form chlorophyll. Porphyrin biosynthesis is one of the most essential biochemical processes in most life forms.

In humans, loss-of-function mutations affecting the first enzyme of the heme biosynthetic pathway, 5-aminolevulinate synthase (ALAS), produce sideroblastic anemia. Gain-of-function mutation of ALAS, and inborn errors that occur at subsequent sites in this pathway, usually result in metabolic disorders known as the *porphyrias* (Fig. 39.1). It has been hypothesized that Vincent van Gogh suffered from porphyria, most likely acute intermittent porphyria, based on the intermittent nature of gastrointestinal complaints, neurological disturbances, and exacerbations caused by inadequate nutrition and absinthe abuse.[2,3]

HEME BIOSYNTHESIS

Biosynthetic Pathways

Heme biosynthesis is an essential pathway and occurs in all metabolically active cells that contain mitochondria. It is most active in erythropoietic tissue, where it is required for hemoglobin synthesis, and in hepatic tissue, where the heme forms the basis of various heme-containing enzymes such as the cytochromes P450, catalase, cytochrome oxidase, and tryptophan pyrrolase. The synthetic pathway starts with the condensation of glycine and succinyl CoA to form 5-aminolevulinate (ALA) under the control of the mitochondrial enzyme ALAS. This enzyme requires pyridoxal phosphate as a cofactor. A series of enzymes then controls the conversion of ALA first to the monopyrrole porphobilinogen (PBG) and then to the various porphyrins. Iron is inserted into protoporphyrin by the enzyme ferrochelatase (FECH) to form heme (see Fig. 39.1). During the past 50 years, complementary deoxyribonucleic acid (cDNA) clones have been obtained for all the enzymes of heme biosynthesis, the structures of the corresponding genes have been determined, and molecular analyses have revealed numerous heterogeneous defects in all the porphyrias. These advances are certain to improve understanding of the pathogenesis of the porphyrias and methods for identification of carriers. The enzymes of the biosynthetic pathway have all been mapped to specific chromosomes (Table 39.1).[4] Heme synthesis and its disorders have been the subject of reviews,[5–7] and advances in our knowledge of mitochondrial iron trafficking and metabolism have recently been reviewed.[8,9]

Control of Heme Biosynthesis

The overproduction of porphyrins and their precursors in the different porphyrias is mainly hepatic or erythropoietic in origin. In the acute porphyrias and in porphyria cutanea tarda (PCT), the liver is the main source of overproduction; in congenital erythropoietic porphyria (CEP), the marrow is the main source; and in erythropoietic protoporphyria (EPP), porphyrins are overproduced by the liver and marrow.

Control of hepatic heme biosynthesis is regulated by the rate of the initial enzymatic step, ALAS1, a housekeeping form of ALAS that is expressed in all cell types, including erythroid cells, whereas ALAS2 encodes a red cell-specific form. ALAS1 is under negative-feedback control by heme, which occurs by more than one mechanism. Heme represses transcription of the ALAS1 gene and increases the rate of degradation of the messenger ribonucleic acid (mRNA) (Fig. 39.2A). At the posttranslational level, heme blocks the translocation of pre-ALAS1 into the mitochondrion.[10] In the mitochondrion, the molecular mass of ALAS1 is smaller than that of the cytosolic pre-ALAS1[10] because of the removal of the mitochondrial targeting sequence. Finally, heme regulates levels of mature ALAS1 by activation of a mitochondrial proteolysis system.[11]

The erythroid bone marrow is the major heme-forming tissue in the body, producing 85% of the daily heme requirement. Heme synthesis in erythroid cells varies from that in hepatocytes; it is linked to tissue differentiation, and the half-life of the same end product of the two is quite different. Heme complexed with globin is preserved in circulating red blood cells for approximately 120 days, whereas heme produced in liver for cytochromes and enzymes, such as catalase, is subject to much more rapid turnover, measurable in hours. Regulation in the liver is exquisitely sensitive to fluctuations in intracellular heme levels[12] and responds rapidly to the requirements for synthesis, as described in Fig. 39.2A. However, heme synthesis in the bone marrow shows a more leisurely response. This fundamental difference is explained by the finding of two different tissue-specific isoenzymes and two different cDNAs for human liver or “housekeeping” ALAS1 and erythroid specific ALAS2, which is expressed exclusively in erythroid cells.[13] The gene for ALAS2 has been mapped to the X chromosome and that for the hepatic enzyme to chromosome 3.[13] The ALAS2 gene has 12 exons; exons 4 to 11 encode the catalytic domain of the enzyme and include a lysine residue that forms a Schiff base with the pyridoxal phosphate cofactor. Exon 1 contributes to the 5′ untranslated region (UTR) whose structure allows iron to regulate ALAS2 mRNA translation, whereas exons 1 and 2 contribute the sequence that targets the enzyme to the mitochondria and is cleaved after import. Succinyl CoA synthetase associates specifically with ALAS2 within the mitochondrion, which helps promote the first step of heme synthesis.[14]

Enzyme levels of ubiquitous and erythroid isoenzymes of ALAS are controlled by different mechanisms. Ubiquitous ALAS1 levels in the liver are regulated by negative feedback by heme that inhibits its gene transcription and import of pre-ALAS1 (see Fig. 39.2A). More recently ALAS1 has been shown to be upregulated by peroxisome proliferator-activated receptor-gamma, coactivator 1, alpha (PPAR-γ coactivator 1-α), which regulates mitochondrial biogenesis and oxidative metabolism. Transcription of PPAR-γ coactivator 1-α is controlled by glucose availability. PPAR-γ coactivator 1-α production increases when glucose levels are low, leading to increased levels of ALAS1 and heme. These conditions are conducive to an acute attack of porphyria. However, the relative contribution of heme and

Figure 39.1 PATHWAY OF HEME BIOSYNTHESIS IN MAMMALIAN CELLS. The first step in the pathway is catalyzed by aminolevulinate synthase (ALAS) and occurs within the mitochondrion using pyridoxal 5′-phosphate as a cofactor. 5-Aminolevulinate (ALA) then leaves the mitochondrion and is converted by ALA dehydratase to give a monopyrrole, porphobilinogen. Four molecules of this compound are converted by porphobilinogen deaminase to a linear tetrapyrrole, hydroxymethylbilane. This molecule is then cyclized by uroporphyrinogen III synthase to uroporphyrinogen III, which is decarboxylated to coproporphyrinogen III. This molecule enters the mitochondrion and is oxidized in succession by coproporphyrinogen III oxidase and protoporphyrinogen oxidase. The product is protoporphyrin IX, a substrate for ferrochelatase, which catalyzes the insertion of Fe^{2+} to form heme. A mitochondrial heme exporter has been identified as feline leukemia virus subgroup C receptor 1b. The defective steps associated with specific porphyrias and X-linked hereditary sideroblastic anemia are shown.

TABLE 39.1 **Porphyrias: Clinical Involvement, Enzymatic Etiology, and Chromosomal Location**

Porphyria (Synonym)	Acute Attack, Skin and Organ Involvement	Enzyme of Heme Biosynthesis Affected (Gene)	Chromosome Location
—	—	Hepatic, 5-aminolevulinate synthase, nonspecific, mitochondrial (ALAS1)	3p21.2
X-linked sideroblastic anemia	Bone marrow	5-Aminolevulinate synthase, erythroid-specific, mitochondrial (ALAS2; low function mutation)	Xp11.21
X-linked dominant protoporphyria	Skin, red cells, liver	5-Aminolevulinate synthase, erythroid-specific, mitochondrial (ALAS2; high function mutation)	Xp11.21
ALA dehydratase deficiency porphyria (plumboporphyria)	Acute liver	ALA dehydratase (ALAD; porphobilinogen synthase)	9q32
Acute intermittent porphyria	Acute liver	Porphobilinogen deaminase (hydroxymethylbilane synthase; HMBS)	11q23.3
Congenital erythropoietic porphyria (Günther disease)	Skin, red cells, bone marrow	Uroporphyrinogen III synthase (UROS)	10q26.2
Porphyria cutanea tarda (symptomatic porphyria, cutaneous hepatic porphyria)	Skin, liver	Uroporphyrinogen decarboxylase (UROD)	1p34.1
Hereditary coproporphyria	Acute skin, liver	Coproporphyrinogen oxidase (CPOX)	3q11.2
Variegate porphyria (porphyria variegata)	Acute skin, liver	Protoporphyrinogen oxidase (PPOX)	1q23.3
Erythropoietic protoporphyria (erythrohepatic protoporphyria)	Skin, red cells, liver	Ferrochelatase (heme synthase; FECH)	18q21.3

ALA, 5-Aminolevulinate.

PPAR-γ coactivator 1-α in regulating ALAS1 expression remains to be resolved.[15,16] In contrast, heme does not affect transcription of the ALAS2 gene, which is under the control of erythroid-specific promoters such as GATA1, a globin transcription factor. Whether heme inhibits import of pre-ALAS2 into the mitochondrial matrix remains to be unequivocally established, although this is supported by in vitro experiments.[17] Heme also regulates the transcription of ferroportin, and H- and L-ferritin during erythroid differentiation, which may ensure adequate iron supply to mitochondria for heme synthesis (see Fig. 39.2B). In addition to transport of iron from plasma to the cytosol by the transferrin receptor, a second transport step is required for mitochondrial uptake of iron. The passage of iron across the outer mitochondrial membrane is ill-defined but is due largely to the presence of voltage-dependent anion channels. Iron import across the inner mitochondrial membrane is fulfilled by mitoferrin,[18] a member of the solute carrier 25 family of proteins located in the inner

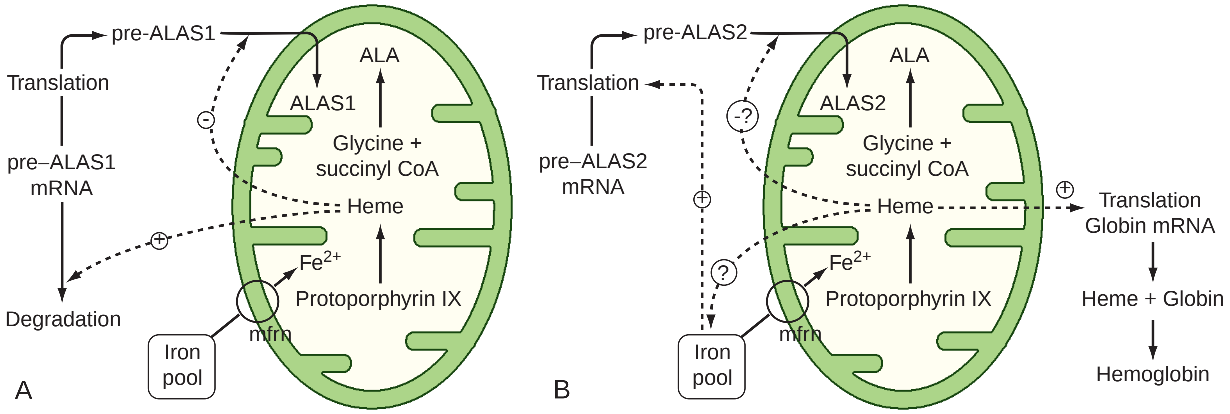

Figure 39.2 (A) Control of heme synthesis in hepatic and other tissues. The rate of heme synthesis depends on the first and rate-limiting enzymatic step catalyzed by 5-aminolevulinate synthase, nonspecific, mitochondrial (ALAS1). Heme represses transcription of the ALAS1 gene, increases the rate of degradation of its messenger ribonucleic acid (mRNA), and blocks the translocation of the ALAS1 isoenzyme into the mitochondrion. (B) Control of heme synthesis in erythroblasts. Cytosolic iron enhances the translation of mRNA of the pre-ALAS2 by inhibiting the interaction of a repressor protein with an iron-responsive element in the mRNA. The product of the last step, heme controls transcription of genes that may contribute to iron metabolism and ensure adequate supply of iron to the mitochondrion. Heme also may inhibit translocation of ALAS2 into the mitochondrion. The overall result is that the rate of heme synthesis is tightly linked to the availability of iron for the ferrochelatase reaction. Mitoferrin (mfrn) transports Fe^{2+} into the mitochondrial matrix. *ALA*, 5-Aminolevulinate.

mitochondrial membrane, which, to import iron into the mitochondrion, must interact both with FECH and with the adenosine triphosphate (ATP)-binding cassette transporter ABCB10.[19] Levels of intracellular iron regulate the translation of ALAS2 mRNA. Cellular iron homeostasis is maintained through a posttranscriptional regulatory mechanism, which is mediated by iron regulatory proteins that bind to iron-responsive elements (IRE) in mRNA of target genes to either increase or decrease translation.[20,21] The RNA binding activity of iron-responsive proteins (IRP) is regulated by mitochondrial iron-sulfur cluster synthesis and cytosolic iron levels.[22–24] When iron is available for heme synthesis, translation of ALAS2 is allowed to proceed as a result of decreased IRP binding to the 5′ UTR iron-responsive elements of ALAS2 mRNA. In contrast, under iron-depleted conditions, increased IRP binding to ALAS2 mRNA blocks translation and ensures that ALAS2 and protoporphyrin levels are not produced in excess of available iron. Furthermore, to prevent the cell from becoming iron deficient, increased translation of mRNA from genes that increase cellular iron, such as the transferrin 1 gene, results from stabilization of mRNA by binding of IRPs to mRNA (see Chapter 36). This effect ensures that protoporphyrin synthesis is coupled to iron availability.

A second rate-limiting step in the overall heme synthetic pathway lies at the level of porphobilinogen deaminase (PBGD), which has a low endogenous activity and is inhibited by protoporphyrinogen and coproporphyrinogen. There are also two forms of PBGD. The PBGD gene (hydroxymethylbilane synthase; HMBS) encodes two enzymes, which arise from alternative splicing of PBGD mRNA. One isoform is expressed in all cells, whereas a second is restricted to red cells.[25] Erythroid PBGD is stimulated by erythropoiesis in vitro and may play a regulatory role in heme biosynthesis during differentiation.[26]

HMBS, the human PBGD gene, has attracted extensive investigation because of the practical importance of detecting carriers of the gene for acute intermittent porphyria (AIP).[27] Studies of the genetic locus of PBGD on chromosome 11 show great molecular heterogeneity,[28] with over 380 mutations associated with AIP in the Human Gene Mutation Database (HGMD Professional 2019, www.hgmd.org). Most human mutations have been described in exons 10 and 12,[29] which is consistent with alteration of the binding sites for the dipyrromethane cofactor for the enzyme. The three-dimensional structure of PBGD has been defined by X-ray crystallography, which has allowed study of the structural and functional implications of mutations.[30]

PORPHYRIAS

Biologic and Molecular Aspects

The porphyrias are classified as acute or nonacute (cutaneous) according to their clinical and biochemical features (Table 39.2).

Each of the different types of porphyria is linked to a reduced activity or deficiency of a specific enzyme in the heme biosynthetic pathway, with the exception of X-linked dominant erythropoietic protoporphyria, which results from inheritance of a gain-of-function mutation in the ALAS2 gene (see Fig. 39.1).[31] When porphyria is caused by a loss-of-function mutation, the resulting enzyme deficiency impairs the production of the end-product heme, and there is overproduction and increased excretion of the heme precursors formed by the steps before the enzyme defect. There is also a compensatory increase in activity of the initial and rate-controlling enzyme ALAS. In the acute porphyrias, there is overproduction of all the porphyrins and porphyrin precursors (e.g., ALA, PBG) formed proximal to the enzyme defect. The increased excretion of porphyrin precursors in the acute porphyrias is caused by decreased activity of PBGD in these conditions. The decrease can be caused by genetic mutation of the enzyme (in AIP) or by inhibition of PBGD by protoporphyrinogen and coproporphyrinogen in variegate porphyria and hereditary coproporphyria, respectively.[32]

In the nonacute porphyrias, there is overproduction of all porphyrins formed before the enzyme defect but no overproduction of porphyrin precursors. The cause of this lack of overproduction of porphyrin precursors in the nonacute porphyrias is unclear, but it may result from a compensatory increase in the activity of the enzyme PBGD in addition to increased activity of ALAS and site-specific heme synthesis.[33] The pattern of overproduction and excretion of porphyrins and porphyrin precursors in the various porphyrias is shown in Table 39.3. A consequence is that each of the different porphyrias is characterized by a different excretion pattern. Quantitative studies of the different porphyrins and precursors in the urine and feces usually identify the particular type of porphyria. The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of bile (see box on Measurement of Porphyrins and Precursors).

TABLE 39.2 Classification of Porphyrias

Classification	Disease	Biochemistry	Clinical Features
Acute porphyria	Acute intermittent porphyria	Increased ALA and PBG	Acute attack
	Variegate porphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	Hereditary coproporphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	ALA dehydratase deficiency porphyria	Increased ALA; increased porphyrin	Acute and chronic neuropathy
Nonacute porphyria	Porphyria cutanea tarda	Increased porphyrin	Photosensitivity
	Erythropoietic protoporphyria	Increased porphyrin	Photosensitivity
	Congenital erythropoietic porphyria	Increased porphyrin	Photosensitivity
	X-linked dominant protoporphyria	Increased porphyrin	Photosensitivity
Porphyrinurias	Lead, alcohol, iron deficiency anemia, liver disease	Various biochemical manifestations	Various clinical presentations

MEASUREMENT OF PORPHYRINS AND PRECURSORS

PBG quantitation in a random urine sample collected during symptoms is recommended as the initial screening test for the acute porphyrias,[34] whereas plasma fluorescent spectroscopy is the best initial test for diagnosis of cutaneous porphyrias.[35] Diverse techniques such as high-pressure liquid chromatography,[36] quantitative extraction, and various forms of fluorometry are used to measure porphyrins and precursors.[34,37,38] The International Federation of Clinical Chemistry and Laboratory Medicine presents diagnostic information on its website (www.ifcc.org).

The clinical manifestations of an acute attack of porphyria can be explained by dysfunction of the central, peripheral, and autonomic nervous systems. The mechanism by which altered heme synthesis results in dysfunction is unknown, although porphyrin-induced protein aggregation may be a mechanism for both external and internal tissue damage in porphyrias that involve fluorescent porphyrin accumulation.[6]

Perhaps the most likely hypothesis is that the neurologic and muscular manifestations of acute porphyria arise as a result of heme deficiency within the nerve cells, which causes dysfunction of the energy-dependent Na^+/K^+ ATPase. The proposal that axonal dysfunction results from impaired energy metabolism is supported by the findings of axonal membrane depolarization during acute attacks of porphyric neuropathy and reduction in inward rectification between episodes.[39] However, this does not exclude the possibility that ALA may also act as a pharmacologic agent in these diseases, compounding the effects of heme deficiency.[40] ALA has a pro-oxidant effect on rat brain tissues and generates free radical species during its auto-oxidation, and this oxidant stress has been proposed to directly damage myelination by Schwann cells.[41,42] The concept of auto-oxidation or oxidative stress is supported by the hypothesis that manganese excess could contribute to induction of superoxide dismutase[43] and increased indicators of such stress in lead exposure.[44] There is evidence that ALA enters cells by a pathway common to it and γ-aminobutyric acid (GABA).[45]

Genetic Aspects

The enzymatic links and genetic loci in each of the hereditary porphyrias are shown in Table 39.1. Nearly all are inherited as autosomal dominant traits. The Chester porphyria family pedigree (Fig. 39.3) shows autosomal dominant inheritance of acute porphyria with attacks of neurovisceral dysfunction without cutaneous hypersensitivity. This was originally reported as a dual porphyria[46]; however, identification of a heterozygous truncating mutation in the HMBS gene and no mutations in other heme biosynthesis enzymes in affected individuals has confirmed that Chester porphyria is a variant of classic AIP.[47] HMBS is transcribed from two promoters to produce ubiquitous and erythroid specific isoforms. In classic AIP both isoforms

Figure 39.3 THE CHESTER FAMILY PEDIGREE. The propositus, Peter Dobson, was a salmon fisherman from a close-knit community living on the bank of the River Dee, which runs through the city of Chester, UK. Most of the 330 descendants of his marriage in 1888 still live in the city. Many suffered disabling illnesses and psychiatric upsets, which often went unrecognized as porphyria. The family called their illness *Dobson's complaint*. Chester porphyria has recently been confirmed as a variant of acute intermittent porphyria. *Squares* represent male subjects; circles represent females. *Courtesy Giles R. Youngs.*

are deficient; however, in the rare, nonerythroid variant, only the ubiquitous HMBS variant is defective. The rare CEP shows autosomal recessive inheritance. The mutations producing each of the acute porphyrias are heterogeneous at the molecular level and include complete or partial gene deletions, alterations of splicing or stability of mRNA, and missense mutations. In South Africa, the founder effect ensures a predominance of the Arg59Tryp mutation in protoporphyrinogen oxidase, although over 175 other mutations have been reported worldwide.[48–50] Homozygotic or compound heterozygotic inheritance has been found in a number of the porphyrias, as has concurrent inheritance of more than one defect. This may present as two types of porphyria in one family[51] or as two types in one patient.[52,53] Dual porphyrias most commonly arise from a combined deficiency of uroporphyrinogen decarboxylase with PBGD, coproporphyrinogen oxidase, or protoporphyrinogen oxidase.[54]

The prevalence of the different forms varies widely. For example, in northern Europe and North America, approximately 1 of 10,000 individuals carries the gene for AIP, although only about 10% of the affected persons will present with clinical features. It has been suggested that spontaneous mutation accounts for 3% of AIP cases.[55] Variegate porphyria occurs in 1 of 400 white South Africans. There is a reduction in gene frequency in variegate porphyria from generation to generation that suggests that the allele associated with it is selectively deleterious.[56] The same is probably true of the other porphyrias.

Acute Intermittent Porphyria

Clinical and Laboratory Manifestations

Acute intermittent porphyria is the most severe of the acute porphyrias. During an attack, patients display abdominal and neuropsychiatric or neurovisceral disturbances. Onset occurs in puberty; female patients exhibit a fourfold greater incidence of attacks than males. Attacks occur mainly in young adults and become less frequent after menopause. It is uncommon to see attacks in children.[57] Crises may vary in duration from several days to months. They are most commonly followed by complete remission, although deaths are still reported, especially with AIP (see box on Precipitating Factors in Acute Porphyria).[58] Late complications of AIP include renal impairment, hypertension, and hepatocellular carcinoma, and patients should be monitored for these complications.[59,60]

Gastrointestinal symptoms occur in 95% of cases; most patients present with acute colicky central abdominal pain. Examination reveals tenderness but little rigidity, and patients may also experience limb pain or generalized muscular aches. Severe vomiting may occur, and constipation is usual. Hyponatremia occurs in severe attacks.

Motor neuropathy complicates two-thirds of porphyric attacks and may be the presenting feature. Motor involvement is most common, but paresthesias may also occur. Paralysis usually starts peripherally and then spreads proximally; however, in some patients, shoulder girdle involvement may be the first manifestation. The neuropathy may progress rapidly, resulting in respiratory insufficiency. Weakness, usually symmetric, involves proximal and distal limb muscles more often than those of the trunk. Upper limbs and proximal muscles are often affected. Involvement of the wrists, ankles, and small muscles of the hand may lead to a permanent deformity (Fig. 39.4), and trunk muscle weakness can lead to respiratory embarrassment. Death is usually caused by respiratory paralysis. Progressive weakening of the voice may suggest this; treatment requires tracheotomy and intermittent positive pressure ventilation. Paresthesias, numbness, and objective evidence of sensory impairment may occur with loss of pinprick

PRECIPITATING FACTORS IN ACUTE PORPHYRIA

Most patients who have inherited acute porphyria enjoy normal health and go through life without any knowledge of their disorder or ever experiencing an acute attack. All porphyric patients, however, are at risk for developing an attack if exposed to various precipitating factors. Drugs are the most common precipitating agents. Other factors that may trigger attacks include alcohol ingestion, reduced caloric intake (from fasting or dieting), and infection. Smoking can cause more frequent attacks.

Hormonal status is also important. Attacks are more common in females, and they rarely occur before puberty or after menopause. Although generally uncomplicated, pregnancy in addition to oral contraceptives may precipitate attacks.[61] Some women experience regular attacks, commencing in the week before the onset of menstruation. These may require luteinizing hormone–releasing hormone (LH-RH) antagonists for control (Table 39.4).

Drugs for Porphyria

Before prescribing any medication to a porphyric patient, advice must be sought from an appropriate specialist. Full drug lists are available on the Internet at https://porphyriafoundation.org/ (in the United States) and www.porphyria-europe.com (in European Union countries, South Africa, and Canada), and a guide for drug prescription at www.drugs-porphyria.org. It should be borne in mind that such lists are far from encyclopedic, that new drugs are constantly being introduced to the pharmacopeia, and that any form of combined preparation must be viewed with suspicion, because little is known about metabolic interactions in these diseases.[62] More details of such use and side effects of drugs can be sought from the literature.[63]

sensation, which is most marked around the shoulder and hip areas; generalized tonic-clonic seizures occasionally occur.

Severe anxiety, depression, and frank psychosis are the main psychiatric manifestations of porphyric attacks. These psychiatric manifestations may result in a patient being misdiagnosed as suffering from a primary psychiatric disorder. Agitation, mania, depression, hallucinations, and schizophrenic-like behavior may occur. Psychiatric manifestations may persist between attacks.[64] Quality of life is severely affected in those suffering from repeated attacks of acute porphyria.[65]

The cardiovascular system is involved in approximately 70% of attacks. Sinus tachycardia (to 160 beats/min) and hypertension can occur; these elevations usually revert to normal after an attack. There is evidence that hypertension may occasionally be permanent, even in latent cases of AIP (see box on Differential Diagnosis of Acute Intermittent Porphyria).

Other Acute Porphyrias

Hereditary Coproporphyria

Hereditary coproporphyria combines the clinical features of acute porphyria with photosensitive skin manifestations. It results from various mutations in the gene encoding coproporphyrinogen oxidase, the activity of which is decreased,[69,70] leading to overproduction of coproporphyrin.[71] A clinically distinct variant of hereditary coproporphyria, harderoporphyria, is associated with severe jaundice and hemolysis and is caused by specific mutations that lead to accumulation of harderoporphyrins.[72]

The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of bile.

Variegate Porphyria

Variegate porphyria is similar to hereditary coproporphyria, except that there are more severe skin lesions, sometimes with scarring (Fig. 39.5). Protoporphyrinogen oxidase is the affected enzyme, and protoporphyrin is the major circulating porphyrin. Conventionally, variegate porphyria is most readily diagnosed by measurement of fecal porphyrin concentrations. However, it has been reported[73] that biliary porphyrin levels may provide a better discriminator from normal patients in the asymptomatic phase. As in erythropoietic protoporphyria, there is a tendency toward cholelithiasis. The mechanism by which gallstones form is not certain, but some studies have suggested that porphyrins are cholestatic.[74] In hereditary coproporphyria and variegate porphyria, the pathway intermediates produced in excess, coproporphyrinogen and protoporphyrinogen, respectively, are inhibitors of the secondary rate-controlling enzyme PBGD.[75,76] Numerous mutations in the protoporphyrinogen oxidase gene have been described leading to 50% reduction in enzyme activity. The functional consequences of many of these mutations have been predicted based on the crystal structure of the enzyme.[77] In a few cases, homozygosity or compound heterozygosity has been described.[49,78]

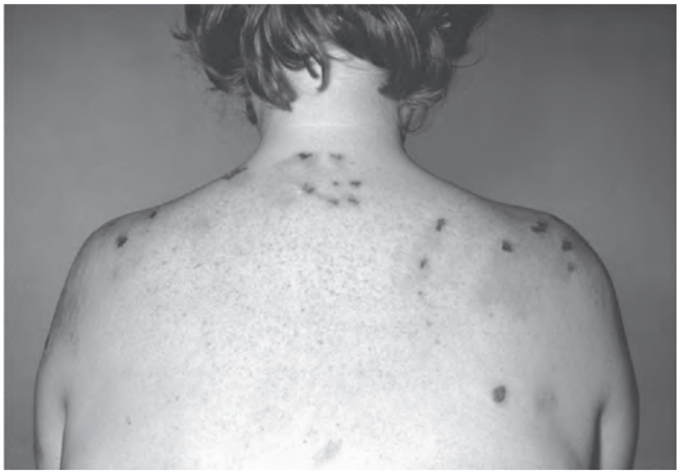

Figure 39.5 CUTANEOUS LESIONS AND SCARRING IN A PATIENT WITH VARIEGATE PORPHYRIA.

DIFFERENTIAL DIAGNOSIS OF ACUTE INTERMITTENT PORPHYRIA

Attacks of acute porphyria must be distinguished from other causes of acute abdominal pain or peripheral neuropathy sometimes associated with psychosis.[66,67] Heavy metal poisoning (i.e., lead or arsenic) and Guillain-Barré syndrome must be considered, as well as paroxysmal nocturnal hemoglobinuria with its characteristic early morning hemoglobinuria and abdominal pain.[7]

During an attack, all patients excrete a massive excess of the porphyrin precursors, 5-aminolevulinate (ALA) and porphobilinogen (PBG), in their urine. Urine, when first voided, is clear and darkens on exposure to light as the hexahydroporphyrins, the porphyrinogens, are oxidized to porphyrins.

A rapid screening test during an acute attack is to mix equal volumes of urine and Ehrlich aldehyde reagent and observe for the pink color of porphobilinogen; alternatively, the urine can be left standing in sunlight to observe darkening in color. The differential diagnosis of porphyrias uses qualitative and quantitative measurement of porphyrins and precursors, with subsequent use of enzymatic assay and identification of familial genetic alterations.[34,68]

5-Aminolevulinate Dehydratase Deficiency Porphyria

In this porphyria (also known as acute hepatic porphyria or plumboporphyria), the ALA dehydratase activity is depressed, such as seen with a low-function variant of the enzyme in a subject exposed to lead. The clinical picture resembles AIP, but very few cases have been described, and the disease only manifests in homozygous cases when there is a precipitating factor.[79,80]

Concurrent Porphyrias

The concurrent porphyrias are a rare group of conditions in which there is concurrent inheritance of two different defects within the heme biosynthetic pathway, although this requires confirmation from molecular evidence.[81] Previous descriptions[52–54] have shown the presence of concurrent porphyria within a family, and toxicologically there is good evidence that exposure to poisons such as lead can induce multiple changes within the pathway.[82] The first reported example of concurrent porphyria in a family combined the clinical features of acute and cutaneous porphyria, and biochemical analysis confirmed the segregation of variegate porphyria and PCT as independent inherited traits.[83] In another patient, dual genetic defects involving ALA dehydratase and coproporphyrinogen oxidase have been described (see box on Management of Acute Porphyria).[52]

Nonacute or Cutaneous Porphyrias

In all cutaneous porphyrias, porphyrins (which are photosensitizing) are deposited in the upper layers of the skin, and they are responsible for the characteristic skin lesions.[90] In the development of these lesions, reactive oxygen species and other radicals are formed and probably induce oxidative membrane damage, particularly to mast cells, which enables complement activation as one part of the inflammatory reaction (see box on Management of Nonacute Porphyria.[91]

MANAGEMENT OF ACUTE PORPHYRIA

Treatment of Acute Attack

A carbohydrate intake of 1500–2000 kcal/24 h should be maintained throughout the attack to reduce porphyrin synthesis; give this orally or, for more severe attacks, through a fine-bore Teflon nasogastric tube. If this cannot be tolerated, intravenous dextrose (e.g., 20% solution, 2 L/day) should be given. If early in the attack (2–4 days from onset), give intravenous hematin as heme arginate (Normosang, Recordati Rare Diseases, Lebanon, NJ) at a recommended daily dose of 3 mg/kg once daily for four days to further reduce the overproduction of porphyrin and precursors.[84,85] Hematin (Panhematin, Recordati Rare Diseases) in similar doses may also be used, although it should be reconstituted in human albumin solution to avoid phlebitis and mild transient prolongation of coagulation times. No renal complications have occurred with the standard recommended dosages, and even patients with renal insufficiency tolerate hematin well, although the dosage should be reduced slightly. Severe hepatic toxicity has been associated with rapid infusion of higher doses of heme arginate.[86] The action of heme therapy may be extended by heme oxygenase blockers such as tin protoporphyrin.[85] Liver transplantation may be an effective treatment for life-threatening acute intermittent porphyria that fails to respond to medical therapy.[87]

Prophylaxis

Many drugs are contraindicated, and the patient must be warned to avoid precipitating factors. Alcohol should be restricted and smoking discouraged. Dieting (<800 kcal/day) must be avoided. Pregnancy should also be avoided if the disease is active. If a patient requires an anesthetic, nitrous oxide, ether, and cyclopropane are safe, and suxamethonium appears to be a safe muscle relaxant. The opiates and belladonna derivatives can be used for premedication and propofol for maintenance of anesthesia. Infection can precipitate an attack and should therefore be sought and treated. Blood relatives of patients should be screened to see if they carry the gene.

Luteinizing hormone-releasing hormone (LH-RH) antagonists that suppress ovulation are a valuable form of prophylaxis in menstrually related attacks.[88] Estrogens and progestogens such as those in the contraceptive pill must be avoided in acute porphyria. The same applies to most steroids and receptor antagonists such as mifepristone.[89]

Porphyria Cutanea Tarda

Biologic and Molecular Aspects

PCT exists in inherited and acquired/sporadic forms. Type I, or sporadic PCT, comprises 70% to 80% of cases and is associated with 50% level of uroporphyrinogen decarboxylase activity. PCT type II or familial PCT results from heterozygous mutations in uroporphyrinogen decarboxylase, whereas a more severe form, hepatoerythropoietic porphyria (HEP), results from homozygous or compound heterozygous mutations.[106] Mutations in the uroporphyrinogen decarboxylase are found in around one-third of patients with PCT. In inherited and acquired forms, there is diminution in the activity of hepatic uroporphyrinogen decarboxylase, which converts uroporphyrinogen to coproporphyrinogen by the stepwise decarboxylation of the acetyl groups to methyl groups. The mechanism of enzyme inhibition has been elucidated, whereby iron-dependent oxidation of uroporphyrinogen generates uroporphomethene, a competitive inhibitor of uroporphyrinogen decarboxylase.[107] Most carriers of mutant uroporphyrinogen decarboxylase are not clinically evident unless precipitating factors are present. Iron alone or chlorinated hydrocarbons can diminish activity of uroporphyrinogen decarboxylase, and this effect is greatly potentiated when both are given together.[108,109] In a murine model, precipitation of uroporphyria by chlorinated hydrocarbons is dependent on hepatic cytochrome P450 Cyp 1A2 oxidase activity, and inherited variations in enzyme function may modulate susceptibility to PCT in humans.[108]

MANAGEMENT OF NONACUTE PORPHYRIA

Patients should avoid exposure to sunlight and use sunblock (to filter Soret band light) and physical barriers such as cotton gloves.

Porphyria Cutanea Tarda

The clinical features are reversed by removing any precipitating agent such as alcohol, halogenated hydrocarbons, and drugs. The patient should be screened for hepatic neoplasm and hepatitis C infection. The mainstay of treatment is to remove liver iron by venesection of 500 mL of blood weekly until clinical remission occurs or until the hemoglobin level falls below 12 g/dL. In patients with PCT where HCV is the primary risk factor, antiviral treatment with direct-acting antiviral agents such as simeprevir and sofosbuvir, is effective as a single-agent therapy.[92,93] Chloroquine, at low doses of 125 mg twice per week for several months, has also been helpful because it enhances urinary clearance of porphyrin. When this is not possible, oral cimetidine has been used.[94] When venesection is difficult, parenteral and orally active iron chelators can be used to reduce liver iron stores. It is of value to screen the patient and first-degree relatives for hereditary hemochromatosis.

Erythropoietic Protoporphyria

Oral β-carotene offers effective protection in erythropoietic protoporphyria (EPP) against solar sensitivity. It does so by quenching the radical formation that is a feature of the skin damage. Yellowing of the skin (i.e., carotenemia) is one side effect. Afamelanotide, an alpha-melanocyte-stimulating hormone that is now approved by the US Food and Drug Administration,[95] is effective for decreasing photosensitivity in EPP by increasing melanin production, and has shown efficacy and tolerability for the long-term treatment of EPP.[96,97] Interruption of the enterohepatic protoporphyrin circulation by bile salt–sequestering agents, such as cholestyramine, reduces plasma protoporphyrin levels and may retard the development of the liver disease. Liver transplantation has been reported to be an effective measure in preventing the progression of this disease.[98,99]

Congenital Erythropoietic Porphyria

The severity of hematologic manifestations are predictors of a poor prognosis, and patients with hemolytic anemia or thrombocytopenia should be considered for allogeneic hematopoietic stem cell transplantation (HSCT). The majority of patients treated with allogeneic HSCT have achieved long-term symptomatic cures.[100,101] Erythropoiesis should be reduced by means of erythrocyte hypertransfusion and by hematin or heme arginate infusion.[102] However, care should be taken when prescribing heme arginate, as overdosing may cause acute hepatic failure.[86] Splenectomy and chloroquine therapy (125 mg twice weekly) have an ameliorating effect, as does hypertransfusion, but life expectancy is usually severely shortened. Iron chelation with deferasirox to inhibit ALAS2 mRNA translation in a CEP patient has resulted in decreased porphyrin accumulation and reduced hemolysis and photosensitivity.[103] Therapeutic potential has been shown with the use of clinically approved proteasome inhibitors, such as bortezomib, which prevent enzymatically active uroporphyrinogen III synthase (UROS) mutants from early degradation in a murine model, and gene therapy using induced pluripotent stem cells.[104,105]

In sporadic (type I) PCT, there is no evident genetic basis for the condition, and low uroporphyrinogen decarboxylase activity is restricted to the liver. Patients may have clinical and biochemical evidence of liver disease. Hepatic siderosis invariably occurs, and iron is one of the causative agents in acquired PCT. An association of PCT with hereditary hemochromatosis has been documented, with about 20% of PCT patients being homozygous for the Cys282Tyr mutation in the HFE ("High Fe") gene, a defect that characterizes hereditary hemochromatosis.[110–112] These results strongly implicate the HFE gene as a genetic susceptibility factor in acquired PCT. An association between PCT and hepatitis C infection is well documented, and in countries with high prevalence rates, hepatitis C virus may be the dominant risk factor.[113] An apparent association has emerged between human immunodeficiency virus (HIV) infection and PCT.[114] It is possible that therapy for HIV with zidovudine precipitates the disease, but it is more likely that the association is merely coincidental or that the viral infection unmasks the preexisting uroporphyrinogen decarboxylase defect.[115]

Genetics

Whereas familial PCT is inherited in an autosomal-dominant mode, HEP is inherited in an autosomal-recessive pattern.[116] As in the other genetic lesions in the porphyrias, there is heterogeneity in the mutations causing PCT and HEP phenotypes.[117,118] In the inherited form, more than 120 different mutations (HGMD Professional 2019, www.hgmd.org) have been identified in uroporphyrinogen decarboxylase, many of which lie near the dimer interface, resulting in an unstable protein and reduced enzyme activity.[119] In different population groups, it is difficult to find the relative numbers of acquired and familial disease. In one analysis in Hungary, 77.5% of patients were found to suffer from the acquired form, and of the patients with the familial disease, females were affected more than males, suggesting that inheritance may predispose patients to estrogen-precipitated disease.[120]

Clinical Features

The most striking clinical feature of both forms of PCT is a bullous dermatosis on light-exposed areas. This starts as erythema and progresses to vesicles that become confluent to form bullae (Fig. 39.6), which may hemorrhage and leave scars; pruritus is often troublesome. Milia are common and may precede or follow vesicle formation. Facial hypertrichosis is common and may serve as a diagnostic clue. In less severe cases, increased fragility of the skin may be the only clinical sign. In severe cases, photomutilation can result, usually because of infection of slowly healing lesions.

The thickening and scarring with calcification have been described as pseudoscleroderma. Hyperpigmentation is common, and women often complain of hirsutism. Neurologic change is not observed. Patients may have clinical and biochemical evidence of chronic liver disease, sometimes with cirrhosis. There is an association with hepatocellular carcinoma. Hepatomegaly is particularly common when alcohol intake is excessive.

Precipitating Factors

Many patients with PCT have multiple precipitating factors, including mutations of the HFE gene, hepatitis C infection, or exposure to estrogen.[111,113] Excessive alcohol intake is an important precipitating agent, perhaps because of increased hepatic iron deposition in alcoholics. However, certain halogenated hydrocarbons are sometimes implicated. PCT may also develop in people treated with hemodialysis for kidney failure. An outbreak of cutaneous hepatic porphyria in southeast Turkey in 1956 was traced to seed wheat dressed with the fungicide hexachlorobenzene. A neoplastic subgroup has been identified in which PCT is associated with benign or malignant liver tumors.

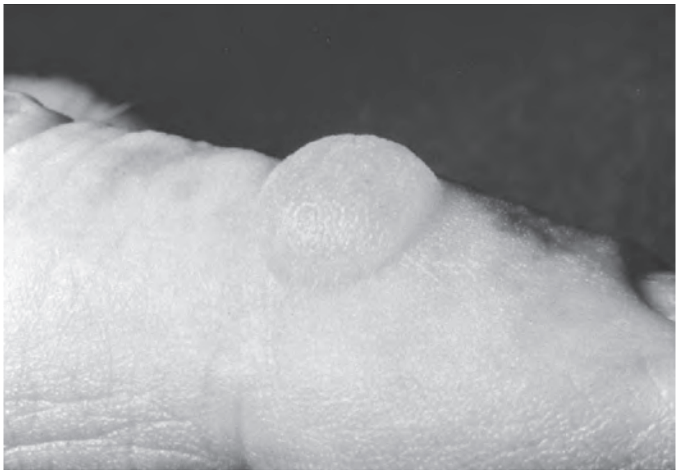

Figure 39.6 A BULLOUS SKIN LESION OF PORPHYRIA CUTANEA TARDA.

Differential Diagnosis

Other causes of bullous or vesicular skin lesions should be excluded, such as a drug reaction (see box on Pseudoporphyria and Renal Dialysis) or chronic renal failure. The distinction between PCT, variegate porphyria, and hereditary coproporphyria rests on biochemical testing of urine and feces, with the highest levels of urinary uroporphyrin found during attacks of PCT (see Table 39.3).

Erythropoietic Protoporphyria and X-Linked Protoporphyria

Biologic and Molecular Aspects

Although not described until 1961, EPP, also known as erythrohepatic protoporphyria, is much more common than CEP. FECH activity is reduced in peripheral blood, liver, bone marrow, and skin, and protoporphyrin is synthesized in excess.[124] Defects in the gene-encoding FECH are the usual cause of EPP; however, a gain-of-function variant in ALAS2, which causes X-linked protoporphyria (XLP),[31] and mutations in the CLPX gene that encodes a mitochondrial protein unfoldase,[125] both cause an identical EPP phenotype. The erythroid progenitor cells (i.e., burst-forming units-erythroid [BFU-E]) in EPP patients show intense fluorescence when viewed under 405-nm light. The gene mutation in EPP shows heterogeneity as in other porphyrias.[126] The last enzyme of the biosynthetic pathway, FECH, is important because its endogenous activity is relatively low, and it could act as a control point in the pathway. FECH ligates iron bound to three cysteine residues in an iron-sulfur cluster,[127] the mutation of which leads to decreased enzyme activity.[128] An oligomeric complex of FECH, ABCB10, and mitoferrin in the mitochondrial membrane would allow for channeling of iron from the cytoplasm to the mitochondrial matrix.[129] Immunologic studies on human protoporphyria show that immunologically reactive FECH is present, but that enzyme activity in three subjects was on average only 17% of normal.[130]

Genetics

EPP inheritance resembles an autosomal dominant disorder with incomplete penetrance; however, the disease usually results from

PSEUDOPORPHYRIA AND RENAL DIALYSIS

The term *pseudoporphyria* has been used to describe a bullous dermatosis associated with a number of dermatologic conditions that bear some resemblance to porphyria.[121] This photosensitivity is often induced by drugs such as the tetracyclines, naproxen, furosemide, voriconazole, oxaprozin, and many others. In these conditions, there is no alteration in porphyrin metabolism or excretion. It is therefore incorrect to name any of them porphyria; the term *pseudoporphyria* should not be applied to them, but only to conditions in which alterations of porphyrin metabolism can be found, such as the bullous dermatosis of hemodialysis

Patients with renal failure can present with many biochemical features of porphyria before hemodialysis. These abnormalities normalize after dialysis, especially when electrolyte abnormalities such as zinc deficiency are also corrected.[122] In a considerable proportion of patients with chronic renal failure, skin changes resembling porphyria cutanea tarda (PCT) develop some months to years after the onset of maintenance hemodialysis. In a minor proportion, genuine PCT can be diagnosed.[123] In such cases, there are elevated total porphyrin levels in plasma and in urine if the patient is not anuric. These patients present a therapeutic dilemma because they are normally anemic and unsuitable for phlebotomy therapy.

inheritance of a FECH null allele together with a low-expression mutation.[131] Haplotype segregation analysis has shown intronic nucleotide polymorphisms in the FECH gene that produces aberrant splicing of mRNA to a form that degrades more rapidly, resulting in enzyme deficiency.[131] Although these disease-associated polymorphisms are common,[132,133] there is heterogeneity of the molecular defect, including aberrant splicing and loss of function of the mitoferrin protein.[124,129,134,135] The erythroid-specific ALAS2 gene resides on the X chromosome, and mutations in exon 11 have been described in X-linked dominant erythropoietic protoporphyria. Recombinant mutants have been shown to increase enzyme activity by two- to threefold, which leads to protoporphyrin overproduction.[136] The XLP genetic variant accounts for 10% of patients with an EPP phenotype in the United States.[137] Five gain of function mutations have been identified in the ALAS2 gene, which is located on the X chromosome.[138] The penetrance and severity of the phenotype in heterozygous females varies due to the pattern of X-chromosome inactivation.[139] In one family, a dominant missense mutation in CLPX has been described that results in marked accumulation of zinc and free protoporphyrin.[125]

Clinical Features

The clinical features are mainly cutaneous on exposure to sunlight and can occur at any age, including infancy and childhood.[140] They include pruritic urticarial swelling and redness of the skin on exposure to sunlight. The most distressing symptom is an unbearable burning sensation on the affected parts. Remarkably, such features are ameliorated during pregnancy, which has been linked to lowered protoporphyrin levels.[141] Hepatic involvement, which occurs in later life, involves deposition of hepatotoxic protoporphyrin in the liver and can lead to fatal liver failure from an active chronic hepatitis with cirrhosis.[142] Such protoporphyrin deposition may also cause cholelithiasis; the gallstones contain high concentrations of protoporphyrin. The liver disease of EPP seems to correlate with erythrocyte protoporphyrin concentrations.[143] Mild microcytic anemia has been reported,[144,145] as well as mitochondrial iron accumulation and ring sideroblasts, in about 30% of patients.[146] Late onset of EPP has been reported in patients with myelodysplastic syndrome or overlap myelodysplasia/myeloproliferation. In one patient, EPP had been acquired as a result of expansion of hemopoietic cells containing only one allele of the FECH gene.[147] Inactivation of one allele by deletion involving chromosome 18 thus appears to be sufficient for overproduction of protoporphyrin.[146,148]

Differential Diagnosis

EPP should be distinguished from other causes of a photosensitive rash. The distinction can be made by demonstrating fluorescence in a proportion of red cells (i.e., fluorocytes) in the peripheral blood and confirmed by measurement of greatly increased erythrocyte and fecal protoporphyrin. Patients with EPP have a relatively high incidence of ring sideroblasts in the marrow.[146] This can lead to diagnostic difficulty because some patients with idiopathic sideroblastic anemia have increased levels of erythrocyte protoporphyrin.[149–152] However, EPP can be distinguished by the autosomal dominant inheritance pattern, dermal photosensitivity, normal or low serum levels of iron, and levels of protoporphyrin in red blood cells and feces.

Congenital Erythropoietic Porphyria (Günther Disease)

Biologic and Molecular Aspects

Congenital erythropoietic porphyria (CEP), or Günther disease, although extremely rare, was the first porphyria to be described in 1874.[153] Unlike the other porphyrias, it is inherited in a mendelian autosomal recessive pattern causing reduced activity of uroporphyrinogen III synthase. The onset of solar photosensitivity results from gross overproduction of porphyrins, caused by deficiency of uroporphyrinogen III synthase. Like other porphyrias, the defective enzyme results mainly from point mutations at multiple sites within the gene.[154] Other enzymes are largely normal, although mutations in the X-linked erythroid transcription factor GATA-binding protein 1 have been reported,[155] and there may be an increase in ALAS activity, which in some cases has been shown to result from gain-of-function mutations in the ALAS2 gene.[156] Excess porphyrins, particularly uroporphyrin-1, accumulate in the normoblasts of the bone marrow and are excreted in the urine and feces. They are also deposited in bones and teeth, resulting in a pink-brown discoloration that fluoresces bright red in light of wavelengths around 400 nm. Dental restoration has been used to correct the esthetic appearance of the teeth. There are frequently profound changes in bone structure in patients with CEP. This has been linked to vitamin D deficiency because of light avoidance.[157] However, bone changes can be seen when vitamin D levels are adequate, and it is reasonable to speculate that the porphyrins deposited in bone are cytotoxic because similar bone changes are features of homozygous variegate porphyria and HEP.[158]

Clinical Features

Typically the onset of CEP is from birth, but occasionally late-onset cases have been reported.[102] The skin reaction is severe and can be devastating, and the teeth become brownish pink because of their high porphyrin content. Severe cutaneous photosensitivity is manifested by blistering of light-exposed areas and fragility of the epidermis. Skin thickening occurs, and there is extensive scarring and hypertrichosis. The recurrent damage associated with scarring on the hand may produce a claw-shaped deformity and loss of digits. Dystrophic nails may curl up and drop off. Lenticular scarring may lead to blindness. Hemolytic anemia often occurs and is associated with increased erythrocyte fragility and splenomegaly. Dyserythropoiesis may contribute to the anemia.[159] One patient who underwent splenectomy at 5 years of age has been described with needle-like inclusions of porphyrin in the circulating red cells (Fig. 39.7).[160]

Differential Diagnosis

The most characteristic feature of CEP is the excess production of series 1 porphyrins rather than series 3 isomer produced in the other porphyrias. Red blood cells fluoresce in ultraviolet light, as do the brown-stained teeth, because of high porphyrin content (see box on Pseudoporphyria and Renal Dialysis).

SIDEROBLASTIC ANEMIAS

Sideroblastic anemias are a heterogeneous group of disorders characterized by anemia of varying severity and diagnosed by finding ring sideroblasts in the bone marrow aspirate. The peripheral blood shows hypochromic red cells, which are microcytic in the hereditary forms (Fig. 39.8A) but are often macrocytic in the acquired forms of the disease. The red blood cell parameters from automated cell counting may show bimodal volume distribution curves or widened range of cell sizes (see Fig. 39.8B); however, this dimorphic size distribution is not always present. Tiny inclusions may be visible in the red blood cells; these can be confirmed as iron-containing Pappenheimer bodies by Prussian blue staining of the blood smear (see Fig. 39.8C). The diagnostic test is bone marrow examination together with Prussian blue staining of the bone marrow smears.

The presence of ring sideroblasts (see Fig. 39.8D) is defined as erythroblasts containing five or more iron-positive (siderotic) granules arranged in a perinuclear collar distribution around one-third or more of the nucleus. Electron microscopic examination has shown that these siderotic granules are mitochondria containing amorphous deposits of ferric phosphate and ferric hydroxide. Iron is also bound to mitochondrial ferritin, a molecular form of ferritin that can be

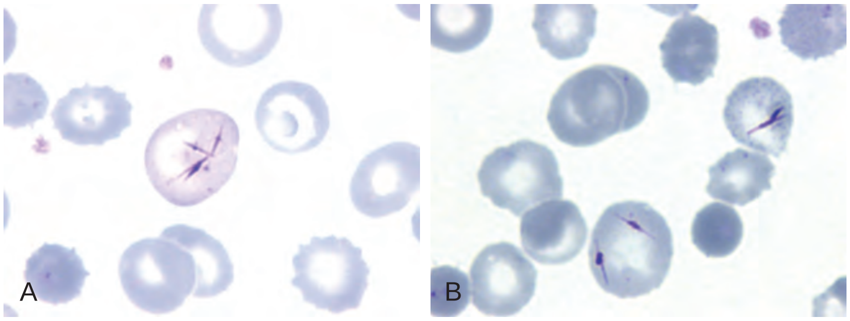

Figure 39.7 NEEDLE-LIKE INCLUSIONS OF PORPHYRIN IN THE CIRCULATING RED CELLS OF A PATIENT WITH CONGENITAL ERYTHROPOIETIC PORPHYRIA AFTER SPLENECTOMY. (A) The red cells contain straight or slightly curved needle-like inclusions that are usually present in a radial orientation but also (B) randomly aligned. *(From Merino A, To-Figueras J, Herrero C. Atypical red cell inclusions in congenital erythropoietic porphyria. Br J Haematol. 2006:132:124.)*

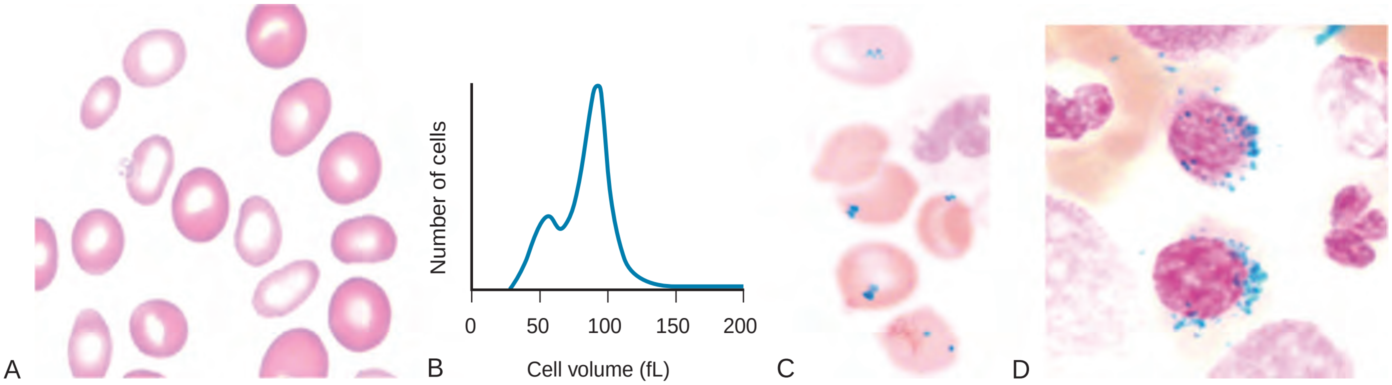

Figure 39.8 (A) Peripheral blood smear from a patient with hereditary sideroblastic anemia shows a population of hypochromic and microcytic erythrocytes. (B) Erythrocyte volume distribution curve of a patient with hereditary sideroblastic anemia. A dimorphic size distribution is evident. distinguished from cytoplasmic ferritin and that accumulates in large amounts in the erythroblasts of subjects with impaired heme synthesis.[161,162]

Iron overload is a common clinical feature of refractory sideroblastic anemia and, in severe cases, may lead to complications that characterize secondary hemosiderosis (e.g., diabetes, cardiac failure). Marrow examination shows prominent erythroid hyperplasia, which is a sign of the ineffective erythropoiesis and is responsible for increased iron absorption by a mechanism that may involve the erythroid factor erythroferrone suppressing hepcidin production.[163] The sideroblastic anemias have diverse causes but have in common an impaired biosynthesis of heme in the erythroid cells of the marrow. Most sideroblastic anemias are acquired as a clonal disorder of erythropoiesis, with various degrees of myelodysplastic features (Table 39.5). The inherited forms are uncommon and occur predominantly in males with an X-linked pattern of inheritance.[164] A number of drugs have been associated with reversible sideroblastic anemia, and ring sideroblasts may be found in patients who abuse alcohol (see Table 39.5). The first descriptions of ring sideroblasts in association with chronic refractory anemias appeared in the late 1950s,[165,166] after an earlier description of familial X-linked hypochromic microcytic anemia.[167]

Hereditary Sideroblastic Anemia

X-Linked Sideroblastic Anemia

Biologic and Molecular Aspects

Almost 40% of congenital sideroblastic anemias are molecularly unexplained.[164,168] Erythroid cells from patients with X-linked forms of hereditary sideroblastic anemia generally exhibit low activity of ALAS2[169]; however, for a minority of ALAS2 mutations this effect may be difficult to detect in vitro.[164] A defect in this enzyme is firmly established in patients whose anemia responds to pyridoxine therapy, because pyridoxal phosphate is an essential cofactor for ALAS2. However, even affected female patients with moderate anemia unresponsive to pyridoxine have been documented to have low levels of ALAS2 in bone marrow lysates. In some male patients with X-linked pyridoxine-responsive sideroblastic anemia, the low ALAS2 activity in bone marrow increased to levels above the normal range when the patient took pyridoxine supplements and recovered from the anemia.[170] There are several possible explanations for this enhancement of ALAS2 activity by dietary pyridoxine supplements. The most likely is that pyridoxine (or its phosphate) may stabilize the ALAS2 during folding of the mutant enzyme after its synthesis.[169] The gene for the ALAS2 isoenzyme has been localized to the X chromosome, and this gene is known to be the site of most mutations giving rise to X-linked pyridoxine-responsive sideroblastic anemia.[168,171] Approximately 100 different mutations have been identified in individuals or families with hereditary sideroblastic anemia, and nearly all have resulted from single base alterations in DNA.[164] A frequent mutation affects arginine at residue 452 of ALAS2, which occurs in a quarter of all pedigrees but does not affect enzyme activity measured in vitro.[172] All known mutations lie between exons 5 and 11 of ALAS2, the region that codes for the catalytic domain, with most lying within exon 9, which contains the lysine at which binding of pyridoxal 5′-phosphate occurs.[173] A mutation, Asp190Val, has been described in a pyridoxine-refractory patient and appears to affect the proteolytic processing of the ALAS2 during or after import into the mitochondrion.[174] The variety of different mutations in the erythroid ALAS2 gene responsible for X-linked sideroblastic anemia and their pyridoxine responsiveness were reviewed in 2019.[164,168]

TABLE 39.5 **Classification of Sideroblastic Anemias**

Hereditary (Nonsyndromic)
X-linked
Autosomal dominant or recessive
Hereditary (Syndromic)
X-linked sideroblastic anemia with ring sideroblasts and cerebellar ataxia
Myopathy, lactic acidosis, and sideroblastic anemia (MLASA1 and MLASA2)
Pearson syndrome
Mitochondrial respiratory protein mutations (thiamine-responsive megaloblastic anemia, MT-ATP6-SA, NDUFB11-SA)
Sideroblastic anemia with immunodeficiency, fevers, and developmental delay
Acquired
Idiopathic acquired[a] (myelodysplastic syndromes with ring sideroblasts)
Associated with previous chemotherapy, irradiation, or in transition myelodysplasia or myeloproliferative diseases
Drugs
Alcohol
Isoniazid
Chloramphenicol
Other drugs
Rare Causes
Erythropoietic protoporphyria
Copper deficiency or zinc overload
Hypothermia

[a] Trial of pyridoxine indicated.

Genetic Aspects

In most families with hereditary sideroblastic anemia, males are affected with an X-linked pattern of inheritance (Fig. 39.9). However, female carriers, although usually normal, can develop erythrocyte dimorphism or varying degrees of anemia. The assignment of the gene for erythroid ALAS2 to the X chromosome[171] and the many mutations documented in erythroid ALAS2 provide the genetic basis for this X-linked disease. In several families, coinheritance of other X-linked traits (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency, ataxia with sideroblastic anemia) has been described.[175,176] Sporadic and familial cases have been described that affect only females, which has been shown to represent skewed X-chromosome inactivation ("unfortunate skewing") affecting the normal allele for the ALAS2 gene.[177] The absence of affected male members in these pedigrees suggests that the ALAS2 defects identified are lethal in hemizygous males.

Clinical and Laboratory Evaluation.

Typically the anemia of X-linked sideroblastic anemia manifests in infancy or childhood, but the milder forms of anemia may not be found until midlife. Even elderly patients have been diagnosed with this anemia.[178] Some cases may be discovered only during family surveys, which should always be undertaken when hereditary sideroblastic anemia is diagnosed. Still other patients may present with features of iron overload, such as diabetes or cardiac failure. Iron overload occurs commonly even with mild anemia and may occasionally be seen with female carriers. Enlargement of the liver and spleen may occur with mild abnormalities of liver function tests.

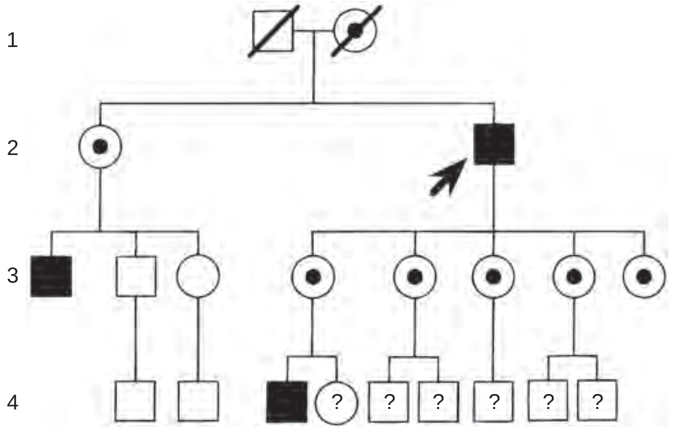

Figure 39.9 PEDIGREE OF A FAMILY WITH PYRIDOXINE-RESPONSIVE SIDEROBLASTIC ANEMIA SHOWING X-LINKED RECESSIVE INHERITANCE. Affected *(filled box)*, carrier *(filled circle within open circle)*, and unknown status *(question mark within circle or box)* are indicated. Diagonal lines indicate deceased members. This pedigree has been abbreviated to show only the affected branches of the family. The arrow indicates the proband.

Anemia is extremely variable, but even when little or no anemia is present, the mean corpuscular volume (MCV) is low, and the red cell volume distribution width may be increased. When anemia is severe, the MCV may be as low as 50 fL (50 μm^3). The blood smear shows a population of cells with hypochromic, microcytic morphology (see Fig. 39.8), which contrasts with the other normochromic, normocytic cells (i.e., dimorphism). Anisocytosis, poikilocytosis, elongated cells, and siderocytes may also be seen. The characteristic erythrocyte dimorphism is most prominent in patients with milder anemia, in female carriers, and in patients in whom pyridoxine has corrected the anemia but not restored the MCV to normal. In some pedigrees with only affected females, macrocytosis may be present, which contrasts with the typical microcytosis of male hemizygotes.[152,177] Leukocyte values are normal, whereas the platelet count is normal or increased.

Serum iron concentration is increased, and transferrin shows an increased percentage of saturation with iron. Serum ferritin levels are invariably increased. Ineffective erythropoiesis can be confirmed by ferrokinetic measurements showing that plasma iron clearance is rapid, with subnormal retention of the iron isotope in erythrocytes after 10 to 14 days. Other features of ineffective erythropoiesis may be variably present: a mild increase in bilirubin concentration, decrease in haptoglobin levels, mild increase in lactate dehydrogenase levels, and normal or slight increase in reticulocyte numbers. The magnitude of iron overload correlates poorly with the degree of anemia in patients who are not transfused. The degree of ineffective erythropoiesis is a better predictor of the amount of iron overload. When ferrokinetics are unavailable, the extent of erythroid hyperplasia relative to normal acts as a rough measure of the magnitude of ineffective erythropoiesis. Several studies have shown that the relative increase in erythroid activity multiplied by the patient's age shows a good correlation with the degree of iron overload as measured by plasma ferritin.[179,180] The iron overload does not result from mutations in the HFE gene (see box on Therapy for Hereditary Sideroblastic Anemia).[181]

Differential Diagnosis

Hereditary sideroblastic anemia should be distinguished from idiopathic hemochromatosis, because both have biochemical evidence of iron overload and a similar tissue pattern of iron deposition. Careful hematologic assessment of patient and family members should make the distinction, because the hemoglobin level and MCV are normal in idiopathic hemochromatosis.

THERAPY FOR HEREDITARY SIDEROBLASTIC ANEMIA

A trial of pyridoxine (100–200 mg/day taken orally) is indicated for 3 months for all patients with hereditary sideroblastic anemia. Response is variable and ranges from complete correction of hemoglobin levels to no effect. Even when pyridoxine completely corrects the anemia (Fig. 39.10), the increase in mean corpuscular volume (MCV) may not reach normal values, and a population of hypochromic, microcytic cells remains.

About 25%–50% of patients with hereditary sideroblastic anemia show a full or partial response to pyridoxine, and this vitamin should be continued on a lifelong basis in the responders. A lower maintenance dose should be determined for each responding patient by progressive dose reduction, because long-term therapy with pyridoxine at 100–200 mg/day has been associated with peripheral neuropathy.[182] The adult nutritional requirement for pyridoxine is 1–2 mg/day; some patients have been maintained on as little as 4 mg/day as a supplement.[170] The anemia of thiamine-responsive megaloblastic anemia usually improves with thiamine 25–75 mg/day.[183] Folic acid supplements should also be administered because the erythroid hyperplasia increases demand for this vitamin.

Allogeneic peripheral blood stem cell transplantation is rarely used in hereditary sideroblastic anemia but has been performed in younger patients.[184,185] Transfusions are the mainstay of treatment for severe anemia unresponsive to pyridoxine. Regular administration of packed red cells using white blood cell filters are given to relieve symptoms and permit normal childhood development. Iron overload and secondary hemosiderosis rapidly progress after transfusions begin; chelation therapy with desferrioxamine or oral deferasirox should be initiated from the onset.

Iron removal may be of great benefit for patients who have mild or moderate anemia and evidence of iron overload.[179,180] These patients can often tolerate intermittent phlebotomy, which in some patients may be preferable to chelation therapy for iron removal, and should be continued to reduce ferritin levels to less than 300 ng/mL. All patients with iron overload should avoid ingestion of ascorbic acid supplements, which enhance iron absorption and increase the tissue toxicity of elemental iron. Alcohol should also be avoided. Splenectomy is contraindicated in this disease.

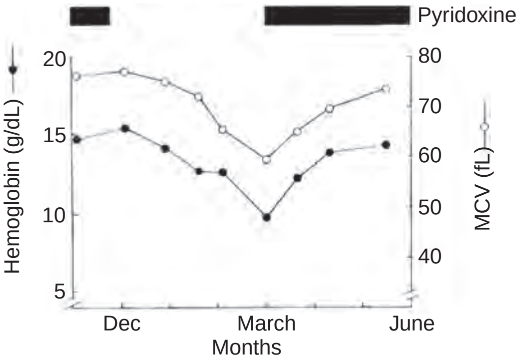

Figure 39.10 RESPONSE OF THE HEMOGLOBIN CONCENTRATION AND MEAN CORPUSCULAR VOLUME (MCV) TO WITHDRAWAL AND REINSTITUTION OF PYRIDOXINE IN A PATIENT WITH RESPONSIVE HEREDITARY SIDEROBLASTIC ANEMIA.

Other Nonsyndromic and Syndromic Hereditary Sideroblastic Anemias

X-linked sideroblastic anemia is considered the most common inherited sideroblastic anemia; however, a number of rare forms have been identified. These consist of nonsyndromic sideroblastic anemias, which cause defects in either heme synthesis or iron-sulfur cluster biogenesis and have similar phenotypes to X-linked sideroblastic anemia, and syndromic forms that cause defective mitochondrial protein synthesis or structure and affect a variety of other tissues in addition to red cells.[164]

Of the nonsyndromic forms, inherited mutations in SLC25A38, the iron-sulfur cluster biogenesis genes, GLRX5 and HSPA9, and FECH have been identified to cause autosomal recessive pyridoxine-refractory sideroblastic anemias.[146,186–188] SLC25A38 is located on chromosome 3p22.1 and encodes a mitochondrial carrier protein that may function to import glycine into the mitochondrion or exchange glycine for 5-aminolevulinate.[188] Homozygous or compound heterozygote mutations in SLC25A38 result in a similar phenotype to that seen in X-linked sideroblastic anemia, with onset in infancy of a severe microcytic anemia that is refractory to treatment with pyridoxine and folic acid. GLRX5 encodes a mitochondrial protein, glutaredoxin 5, which when deleted in the zebrafish mutant shiraz results in defective iron-sulfur cluster assembly and blocked synthesis of heme.[189] A late-onset pyridoxine-refractory sideroblastic anemia caused by homozygous mutation in GLRX5 has been described in a patient who in middle age developed symptoms of a microcytic hypochromic anemia, type 2 diabetes, cirrhosis, and liver iron overload.[187] HSPA9 is a mitochondrial heat shock protein 70 homolog that is involved in transfer of iron-sulfur complexes to mitochondrial glutaredoxin 5. Mutations in HSPA9 cause nonsyndromic microcytic to normocytic sideroblastic anemias.[186]

In addition to genetically defined forms of hereditary sideroblastic anemia, a number of syndromic types have been described, which present with anemia in combination with either muscle, neurologic, or pancreatic tissue involvement. The first of these disorders to be defined by molecular genetics, the Pearson syndrome, is a rare entity that manifests in early infancy with anemia and exocrine pancreatic dysfunction.[190,191] The anemia is normocytic or macrocytic, reticulocyte counts are low, and variable degrees of neutropenia and thrombocytopenia are present. The bone marrow shows striking vacuolation and ring sideroblasts.[191] Although usually fatal, milder forms of the anemia are consistent with survival into adult life. The syndrome, which is related to the Kearns-Sayre syndrome, results from deletions, mutations, or duplications of mitochondrial DNA, variably affecting multiple tissues of the body.[192,193]

A second syndromic congenital sideroblastic anemia, X-linked sideroblastic anemia with cerebellar ataxia (XLSA/A), is a rare mitochondrial disease caused by loss-of-function mutations in the ATP-binding cassette transporter ABCB7.[194–197] ABCB7 is localized to the inner mitochondrial membrane and has been proposed to function as an exporter of mitochondrial iron-sulfur clusters to the cytoplasm[198]; however, a direct role in heme synthesis may arise through an interaction with FECH.[199] Males affected with XLSA/A usually present in infancy with nonprogressive or slowly progressive ataxia and incoordination, which is accompanied by a mild to moderate hypochromic microcytic anemia and the presence of ring sideroblasts on bone marrow examination.

Mutations in the high-affinity thiamine transporter gene SLC19A2, located at 1q24.2, cause the thiamine-responsive megaloblastic anemia (TRMA) syndrome.[200] TRMA has the unusual bone marrow feature of megaloblastic erythroid maturation with ring sideroblasts. TRMA presents with early-onset megaloblastic anemia, diabetes mellitus, and sensorineural deafness, which respond variably to thiamine treatment. Mutations in other mitochondrial respiratory protein genes, including MT-ATP6 and NDUFB11, present in early childhood with lactic acidosis, myopathies, and in the case of MT-ATP6, neurological abnormalities.[201,202]

MLASA1 and MLASA2, are classically characterized by the triad of muscle weakness, lactic acidosis, and normo- to macrocytic anemia. Missense and nonsense mutations in the PUS1 gene coding for pseudouridine synthase-1 cause the rare autosomal recessive disease, myopathy, lactic acidosis, and sideroblastic anemia (MLASA1).[203–205] Mitochondrial and cytoplasmic transfer RNAs (tRNAs) from affected patients lack tRNA pseudouridylation at sites normally modified by PUS1; however, the mechanism by which this affects oxidative phosphorylation and iron metabolism in skeletal muscle and bone marrow are yet to be elucidated.[203] MLASA2 has an identical phenotype caused by a homozygous mutation in the mitochondrial tyrosyl-tRNA synthetase gene, YARS2.[206] The homozygous mutation in YARS2, identified in three patients from two consanguineous Lebanese families, causes defective mitochondrial synthesis and, similar to mutations in PUS1, results in defective oxidative phosphorylation.[206] MLASA1 and MLASA2 usually present with progressive exercise intolerance commencing in childhood followed by later development of sideroblastic anemia, basal lactic acidemia, and mitochondrial myopathy. A biallelic mutation has been described in another mitochondrial protein synthesis gene, LARS2, in a single patient with a related, lethal mitochondrial phenotype that included sideroblastic anemia.[207]

Over a dozen mutations in the TRNT1 gene, which encodes an essential enzyme that transfers the CCA nucleotide repeat to tRNA molecules, result in sideroblastic anemia with B-cell immunodeficiency, periodic fevers, and developmental delay (SIFD).[208,209] This autosomal recessive syndromic disorder manifests as a severe sideroblastic anemia in infancy, recurrent periodic fevers, B-cell lymphopenia, and hypogammaglobulinemia.

Acquired Sideroblastic Anemia

Acquired sideroblastic anemia is categorized within the myelodysplastic syndromes and may appear de novo or occur after chemotherapy or irradiation (see Table 39.5). The clonal nature of hemopoiesis in this condition was first suggested by Dacie et al.[166]

The World Health Organization (WHO) Classification collectively groups myelodysplastic syndromes with ring sideroblasts as “MDS-RS” and distinguishes three categories: MDS with ring sideroblasts and single-lineage dysplasia (MDS-RS-SLD), MDS with ring sideroblasts and multilineage dysplasia (MDS-RS-MLD), and MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T).[210] Many patients with refractory anemia with ring sideroblasts and thrombocytosis have a point mutation in the Janus kinase 2 gene (changing valine-617 to phenylalanine), which is a feature usually associated with the myeloproliferative disorders.[211] This latter group have a clinical phenotype that includes normal MCV, marrow fibrosis, and splenomegaly (see Chapter 61).[211]

Biologic and Molecular Aspects

Clonal hematopoiesis has been demonstrated in acquired idiopathic sideroblastic anemia and in the related myelodysplastic syndromes. Specific evidence was first provided by finding a single G6PD isoenzyme in erythrocytes, granulocytes, platelets, and B lymphocytes in a woman who was heterozygous for G6PD and carried two isoenzymes in her skin and T lymphocytes.[212] This technique is applicable only to the few women who have G6PD heterozygosity, but restriction fragment length polymorphism analysis can be applied to most women using probes directed at other X-chromosome genes, such as that for phosphoglycerate kinase or to an X-linked, variable-copy-number tandem repeat sequence.[213] The results show uniform monoclonality of hematopoiesis in acquired sideroblastic anemia with or without associated myelodysplastic features. Some indirect evidence exists for a primary mitochondrial lesion, perhaps in the mitochondrial respiratory chain, which impairs the reduction of Fe^{3+} because Fe^{2+} is essential for heme synthesis.[214–217] Recurrent mutations in the SF3B1 gene have been described in acquired sideroblastic anemia and are found in 70% to 90% of patients with MDS-RS.[218–220] The product of SF3B1 is associated with mRNA splicing, and mutations in this gene may influence a number of mitochondrial gene networks, including changes in the expression of the iron transporter ABCB7, resulting in iron-laden mitochondria during erythroid development.[221] MDS-RS-T cases have somatic SF3B1 mutations and gain-of-function hematopoietic receptor tyrosine kinase–signaling mutations, most commonly JAK2 valine-617 to phenylalanine, and less commonly other JAK2, MPL, or CALR gene mutations.[222] Genetic mutations in other spliceosome components, including SRSF2, ZRSR2, and PRPF8, are found in MDS-RS lacking SF3B1 mutations[223,224]; however, it is unclear whether these variants play any pathogenic roles in disease development or progression.

Etiology

Clonal chromosomal changes are found in bone marrow cells in approximately 60% of patients with acquired sideroblastic anemia. Characteristic changes are monosomy 7; trisomy 8; deletions involving chromosomes 5, 7, 11, or 20; and a number of balanced translocations.[225] When sideroblastic anemia is acquired after chemotherapy or irradiation, chromosomal changes are usually found and tend to be multiple.[225] Among these changes, the loss of an entire chromosome (5 or 7, or both), deletion of a long arm [del(5), del(7), or del(13)], and an unbalanced translocation are typical.[226,227] When karyotype shows loss of material from chromosomes 5 or 7, or both, a detailed occupational history may show exposure to potentially mutagenic chemical agents in a proportion of patients.[228] However, the development of visible chromosomal changes is probably a late event in acquired sideroblastic anemia and may be preceded by the expansion of a clone of genetically unstable stem cells. This concept is in accord with the view that multiple genetic events underlie the pathogenesis of other myelodysplastic syndromes and acute myeloid leukemia (see box on Clinical and Laboratory Evaluation of Sideroblastic Anemia).[212,229]

Differential Diagnosis

Ring sideroblasts are not limited to acquired sideroblastic anemia; they also occur in other myelodysplastic conditions, such as refractory

CLINICAL AND LABORATORY EVALUATION OF SIDEROBLASTIC ANEMIA

Typically, acquired sideroblastic anemia develops insidiously in a middle-aged or elderly patient with normal or increased mean corpuscular volume (MCV) and a blood smear showing a population of hypochromic red cells. Hepatosplenomegaly may be present. Leukocyte and platelet counts are usually normal, and the presence of a thrombocytosis should prompt investigating for the presence of the JAK2 V617F mutation and MDS-RS-T.[211] If leukopenia or thrombocytopenia is present, a careful search should be made for myelodysplastic features, which lead to the diagnosis of MDS-RS-MLD.[210] An iron stain of the bone marrow aspirate shows ring sideroblasts, which should total 15% or more of all erythroblasts to make the diagnosis of acquired sideroblastic anemia.[210] Iron cannot be assessed in the marrow trephine biopsy core because it may leach out during decalcification.

The bone marrow also shows erythroid hyperplasia. Although mild dyserythropoiesis (e.g., multinuclearity, nuclear budding) and megaloblastoid changes are present, myelopoiesis and megakaryopoiesis are usually normal. When changes are confined to dyserythropoiesis, the condition is defined as MDS-RS-SLD.[210] However, dysplasia of myelopoietic and megakaryopoietic elements may be present (i.e., refractory cytopenia with multilineage dysplasia) with the following features: Pelger-Huët–like anomaly, hypersegmentation or hypogranularity of neutrophils, micromegakaryocytes, large mononuclear megakaryocytes, and megakaryocytes with multiple small nuclei (see Chapter 61). Dysmegakaryopoiesis is more easily detected in trephine biopsies than in marrow smears, although the trephine may also show unsuspected islands of myeloblasts characteristic of myelodysplasia.[230] The overall blast count in marrow smears is, by definition, less than 5%, and the peripheral blood monocyte count is less than 1.0 × 10^9/L. Cytogenetic analysis of marrow aspirates provides important information, because a normal karyotype predicts long survival in any type of acquired sideroblastic anemia.[231]

anemia with excess blasts, in which the blast count is higher than 5%.[210,232] Careful examination of peripheral blood and bone marrow can distinguish acquired idiopathic sideroblastic anemia from these related myelodysplastic conditions. Family surveys are very useful in distinguishing acquired from hereditary forms of sideroblastic anemia, because the latter may present in late adult life.

Prognosis

Using MDS prognostic models, MDS-RS has the most favorable outlook among the myelodysplastic syndromes. The Revised International Prognostic Scoring System (R-IPSS) uses the bone marrow blast percentage, karyotypic analysis, and the presence of peripheral blood cytopenias to group newly diagnosed cases into one of five prognostic groups. Very low-risk patients have a median survival of 8.8 years, low-risk patients 5.3 years, intermediate-risk patients 3 years, high-risk patients 1.6 years, and very high-risk patients 0.8 years.[233] MDS-RS is generally stratified into low-risk groups. For example, in a Mayo Clinic cohort of 48 patients with MDS-RS-SLD using the R-IPSS, 34% were classified as very low, 64% as low, and 2% as intermediate.[234] The median OS for patients with MDS-RS-SLD ranges from 69 to 108 months, with a very low risk for leukemic transformation (<2%).[235] The survival of patients with MDS-RS-MLD is inferior to that of MDS-RS-SLD, but better than that of patients with MDS-MLD.[236] Karyotypic analysis of marrow aspirates provides valuable information, because a normal karyotype carries a more favorable prognosis. Conversely, chromosome 7 abnormalities impart a high probability of transformation to acute myeloid leukemia. Multiple chromosomal abnormalities and del(20q) are also associated with an increased risk for progression to leukemia; in contrast, trisomy 8 has no adverse prognostic significance (see box on Therapy for Acquired Sideroblastic Anemia).[225]

THERAPY FOR ACQUIRED SIDEROBLASTIC ANEMIA

Transfusions are indicated for relief of symptomatic anemia. Erythropoiesis-stimulating agents (ESAs), such as recombinant human erythropoietin (rh-EPO) and darbepoetin, can be used for the treatment of anemia and response rates in lower risk MDS range from 30% to 60%, with the median duration of response being 24 months.[237] Lenalidomide has preferential activity in MDS patients with isolated del(5q) but can also decrease transfusion requirements in MDS-RS-SLD, with 25%–35% of transfusion-dependent patients achieving transfusion independence.[238,239] Furthermore, there is evidence of a synergistic effect of combining lenalidomide with ESAs.[240]

A trial of pyridoxine at 100–200 mg/day for 3 months is worthwhile in patients who have anemia but who do not display neutropenia or thrombocytopenia. However, few patients with acquired idiopathic sideroblastic anemia respond to this vitamin. If any response is achieved, maintenance therapy with pyridoxine at lower dosage is indicated. It is unclear if iron chelation therapy with the oral iron-chelator, deferasirox is of benefit; and until this is established, its routine use is not recommended.

Sotatercept and luspatercept both inhibit molecules in the TGF-β superfamily and increase hemoglobin levels independently of the EPO pathway. Both agents have shown efficacy in reducing transfusion requirements in transfusion-dependent, low-risk MDS-RS patients, and the telomerase inhibitor imetelstat has also shown some activity.[234,241,242] Hypomethylating agents (HMA) such as 5-azacitidine and decitabine can be used in patients that have failed ESA or have developed disease progression, and azacitidine can achieve transfusion independence in up to 40% of patients with lower-risk MDS.[243,244]

Because of the risk of exacerbating anemia, cytoreductive therapy is avoided in MDS-RS-T unless there is a high risk for thrombosis. Hydroxyurea can be used to reduce the platelet count and has been shown to reduce the risk of thrombotic events.[245]

SIDEROBLASTIC ANEMIA AND PORPHYRINURIA CAUSED BY DRUGS

Alcohol

Ring sideroblasts may be found in the bone marrow of malnourished anemic alcoholics, usually in the presence of associated folate deficiency.[246–248] In contrast, binge drinking or chronic alcohol ingestion in subjects with good nutrition is not associated with sideroblastic abnormality. Sideroblastic change is never the sole cause for the anemia of alcoholism. Alcohol has a direct toxic effect on hematopoiesis.[249] An increased or high-normal MCV and vacuolation of red blood cell precursors is often seen in addition to the ring sideroblast abnormality. Red blood cells show dimorphic morphology; evidence in the marrow of folate deficiency is present in half of cases.[249] Transferrin saturation and marrow iron stores tend to be increased but may be low if gastrointestinal bleeding is present. The ring sideroblasts gradually disappear over 4 to 12 days when alcohol is withdrawn[246]; during this period, there may be a rebound erythroid hyperplasia, reticulocytosis, and thrombocytosis. Folic acid should be given for the associated megaloblastic changes after blood is taken for vitamin B_{12} and folate assays.

Alcohol consumption lowers the plasma concentration of pyridoxal phosphate, a cofactor for ALAS2, needed in the first step in heme synthesis.[250] Conversion of ethanol to acetaldehyde is necessary for this effect, and acetaldehyde acts by accelerating the degradation of intracellular pyridoxal phosphate in the liver, lowering plasma levels of this coenzyme.[251]

Chronic alcoholics have an altered heme metabolism with increased urinary excretion of coproporphyrin, mainly isomer III, but normal urinary excretion of uroporphyrin, ALA, and PBG. Acute and chronic ethanol ingestion markedly depresses the activity of ALA dehydratase in peripheral blood. Ethanol administration to normal subjects results in increased activity of leukocyte ALAS and erythrocyte PBGD, the two rate-controlling enzymes of the pathway. The activities of each of the other four enzymes are depressed. FECH, the enzyme that inserts iron into protoporphyrin to form heme, shows the most marked depression, and in alcoholism there is prolonged depression of uroporphyrinogen decarboxylase, which provides a rationale for the role of ethanol in the etiology of PCT.[252,253] As expressed earlier, ethanol is a major precipitating factor in acute porphyria.[254]

Isoniazid

Administration of the antituberculous drug isoniazid has occasionally been associated with development of a sideroblastic anemia after 1 to 10 months of therapy. The anemia is hypochromic and microcytic, with a dimorphic blood smear and ring sideroblasts in the marrow. This complication is thought to occur only in slow acetylators of isoniazid, allowing this drug to react nonenzymatically with pyridoxal and to form a hydrazone that is rapidly excreted in the urine. The anemia can be fully reversed by coadministration of pyridoxine (25 to 50 mg/day) with isoniazid or by withdrawing isoniazid.[255] Another antituberculous drug, pyrazinamide, may also cause a sideroblastic anemia, which is caused by inhibition of ALAS2 and responds to pyridoxine therapy.[256]

Chloramphenicol

Chloramphenicol is an antibiotic that produces a reversible suppression of erythropoiesis after several days of therapy (plasma levels of 10 to 15 µg/mL). This effect is predictable and separate from the rare idiosyncratic side effect of aplastic anemia in approximately 1 of 20,000 exposed persons. Nearly all patients given chloramphenicol (>2 g/day) develop vacuolation of the erythroid precursors and ring sideroblasts. These effects are thought to arise from suppression of mitochondrial respiration. Chloramphenicol inhibits mitochondrial protein synthesis and reduces cytochrome *a*, a_3, and *b* levels.[257] Serum iron concentrations are increased, and reticulocyte numbers are subnormal; these changes revert on stopping the antibiotic.

Other Drugs

A reversible acquired sideroblastic anemia has been described with penicillamine, linezolid, and with the use of triethylene tetramine hydrochloride, a copper-chelating agent used in the treatment of Wilson disease.[258,259] Acquired sideroblastic anemia has also been precipitated by progesterone given to a patient on two separate occasions 15 years apart, and this anemia promptly reversed on withdrawal of the drug.[260]

PRESENTATIONS ASSOCIATED WITH SIDEROBLASTIC ANEMIA OR PORPHYRINURIA

Copper Deficiency or Zinc Overload

The copper content of a Western diet averages 0.9 to 1.6 mg each day, which is only a few times greater than the amount needed to maintain homeostasis of this essential element.[261] Copper deficiency has been described in malnourished premature infants,[262] in patients receiving long-term parenteral or enteral hyperalimentation,[263] after gastrectomy,[264] with copper-chelating agents,[258] or on an idiopathic basis.[265] The syndrome of copper deficiency consists of sideroblastic anemia with hypochromic cells in the blood smear, accompanied by ring sideroblasts and vacuolated erythroid and myeloid precursors in the marrow, and of neutropenia with an absence of late myeloid forms in the marrow (Fig. 39.11). In some reports, patients present with neurologic symptoms such as paresthesias, weakness, or ataxia; and demyelination is seen on the magnetic resonance image of the brain.[265] In infants, additional features may be seen, such as osteoporosis and long bone changes, depigmentation of skin and hair, and central nervous system abnormalities. The platelet counts remain normal. Serum copper and ceruloplasmin levels are low, whereas serum iron and transferrin saturation levels are normal. The serum zinc concentration may be increased.[265] Prompt reversal of the hematologic changes follows therapy with 2 to 5 mg/day of copper sulfate taken orally or 100 to 500 μg/day of copper supplement to the intravenous alimentation formula.

Large quantities of ingested zinc interfere with copper absorption and produce the neutropenia and sideroblastic anemia characteristic of copper deficiency.[266] Zinc sulfate is freely available from health food stores, and as little as 450 mg/day for 2 years is sufficient for this effect. Sideroblastic anemia has also been ascribed to zinc toxicity arising from the ingestion of coins over a period of many years.[267] Serum zinc levels are high, whereas serum copper and ceruloplasmin levels are low. Zinc must be discontinued for 9 to 12 weeks for full reversal of the anemia and neutropenia.

Iron Deficiency Anemia

In iron deficiency anemia, there is an accumulation of protoporphyrin in erythrocytes that rarely reaches the level found in EPP. The zinc complex of protoporphyrin is produced because FECH uses Zn^{2+} during iron-deficient erythropoiesis.[268] Erythrocyte protoporphyrin may be raised before changes appear in peripheral blood and may be helpful in diagnosing iron deficiency when serum iron and ferritin levels are rising as a result of patients having started iron therapy. In iron-deficient erythropoiesis, erythroid ALAS activity is reduced below normal.[269]

Hypothermia

Thrombocytopenia, erythroid hypoplasia, and ring sideroblasts have been described in patients with hypothermia associated with neurologic disease.[270] These changes reverse slowly as body temperature returns to normal.

Other Conditions

In hereditary tyrosinemia, excess urinary ALA is excreted because ALA dehydratase is inhibited by succinyl acetone. Like acute porphyria and lead poisoning, this disease is associated with neurobehavioral disturbance (see box on Lead Poisoning). In liver disease, there may be

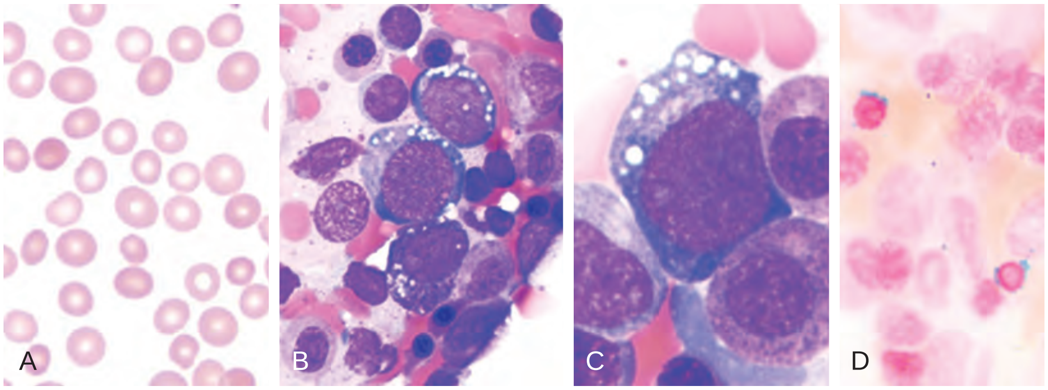

Figure 39.11 This 70-year-old man was being treated with zinc supplementation and was found to have anemia and neutropenia (hemoglobin, 8.3 g/dL; hematocrit, 23.9%; and white blood cell count, 1200/μL). His peripheral smear (A) showed a biphasic erythroid population with some small slightly hypochromic cells and increased anisocytosis (red blood cell distribution width [RDW], 23.9%). The bone marrow aspirate showed a left shift in granulopoiesis with vacuolization of immature granulocytic and erythroid precursors (B, C). A Prussian blue–stained aspirate revealed ring sideroblasts (D). The patient's copper level was less than 0.1 μg/mL (normal reference range, 0.75 to 1.45 μg/mL).

LEAD POISONING

It has been known for some time that patients suffering from lead poisoning have an accumulation of protoporphyrin in erythrocytes and increased urinary excretion of ALA and coproporphyrin.[274] There are sex-related differences in the porphyrin synthetic response to lead, with females showing a more profound coproporphyrinuria than men.[275] The elevated protoporphyrin chelated by zinc is retained in the erythrocyte, which may explain the absence of photosensitivity. This accumulation of porphyrins and precursors is caused by the inhibition by lead of the heme biosynthetic enzymes: 5-aminolevulinate (ALA) dehydratase, coproporphyrinogen oxidase, and ferrochelatase. An increase in the activity of the rate-controlling enzyme ALA synthase (ALAS) results.

Many of the clinical manifestations of lead poisoning may be the result of altered heme biosynthesis.[82] A mild to moderate anemia that can be hypochromic and microcytic occurs in a minority of patients, whereas basophilic stippling is prominent because of inhibition of pyrimidine 5′-nucleotidase in the maturing reticulocyte. Ring sideroblasts have not been reported. The abdominal pain, constipation, and peripheral neuropathy that occur in lead poisoning are also seen in acute attacks of hepatic porphyria. Neuropathy, seen in lead poisoning, may also be the result of disorders of heme biosynthesis, as in the porphyrias.[274] Alterations in porphyrin metabolism have provided a useful means of detecting and assessing the severity of lead exposure and poisoning. The diminution in activity of erythrocyte ALA dehydratase and elevated erythrocyte protoporphyrin levels are the most sensitive measures.

increased urinary excretion of coproporphyrin, predominantly isomer I. In the Dubin-Johnson syndrome, which is caused by mutations in the ABCC2 gene, the ratio of coproporphyrin isomer I to isomer III is markedly increased in the urine (>80%), possibly as a result of deficiency of hepatic uroporphyrinogen III cosynthase and increased activity of PBGD.[271] In Rotor syndrome, total urinary excretion of coproporphyrin is markedly increased and consists predominantly of coproporphyrin isomer I.[272] In the unconjugated hyperbilirubinemia of Gilbert syndrome, depressed activity of protoporphyrinogen oxidase and increased activity of ALAS has been found in peripheral leukocytes.[273]

Environmental Intolerances

It has been hypothesized that several otherwise-unexplained chemical-associated illnesses, such as multiple chemical sensitivity syndrome, may represent mild chronic cases of porphyria or other acquired abnormalities in heme synthesis. However, evidence for this concept is lacking.[275,276]

CHAPTER 40

MEGALOBLASTIC ANEMIAS

Aśok C. Antony

The term *megaloblastic anemia* is used to describe a group of disorders characterized by a distinct morphologic pattern in hematopoietic cells. A common feature is a defect in deoxyribonucleic acid (DNA) synthesis, with lesser alterations in ribonucleic acid (RNA) and protein synthesis, leading to a state of unbalanced cell growth and impaired cell division. Most megaloblastic cells are not resting but vainly engaged in attempting to double their DNA, with frequent arrest in the S phase and lesser degrees of arrest in other phases of the cell cycle. An increased percentage of these cells have DNA values between 2 N (where N is the amount of DNA in the haploid genome) and 4 N because of delayed cell division. This increased DNA content in megaloblastic cells is morphologically expressed as larger-than-normal "immature" nuclei with finely particulate chromatin, whereas the relatively unimpaired RNA and protein synthesis results in large cells with greater "mature" cytoplasm and cell volume. The net result of megaloblastosis is a cell whose nuclear maturation is arrested (immature) while its cytoplasmic maturation apparently proceeds normally independently of the nuclear events. The microscopic appearance of this nuclear-cytoplasmic asynchrony (or dissociation) is morphologically described as megaloblastic. Each cell lineage has a limited but unique repertoire of expression of defective DNA synthesis. This is significantly influenced by the normal patterns of maturation of the affected cell line. Additional variables that affect RNA and protein synthesis can lead to the attenuation or modification of megaloblastic expression (see Masked Megaloblastosis).

Megaloblastic hematopoiesis commonly manifests as anemia, but this feature is only a manifestation of a more global defect in DNA synthesis that affects all proliferating cells. The peripheral blood picture is characteristic and reflective of megaloblastic hematopoiesis within the bone marrow. The diagnosis is therefore usually straightforward, but because any condition that specifically perturbs DNA synthesis may lead to megaloblastosis, determination of the precise cause is necessary before institution of therapy. Inappropriate therapy can lead to disastrous consequences for the patient. The biochemical basis for megaloblastosis needs to be understood within the context of evaluation of potential and real variables affecting DNA, RNA, and protein synthesis in a given patient. The most common causes of megaloblastosis are true cellular deficiencies of vitamin B_{12} (cobalamin) or folate, vitamins that are essential for DNA synthesis.

Because of the imperative for conservation of cobalamin within the body, there is a finely tuned mechanism in place to ensure a sequential handover of this precious cargo from one protein to another—from the point of its entry into the mouth through the gut, across the enterocyte, into the circulation with specialized uptake into cells, passage through lysosomes into cytoplasm, and even into mitochondria. Throughout this odyssey, cobalamin is accompanied by several chaperones that sequentially bind, sequester, and thereby ensure that cobalamin does not participate in side reactions. This ensures its fitness for service for critical enzymes.

Despite the greater abundance of folate in the diet relative to cobalamin, there are also specialized means to ensure that the natural folates in food are first chopped and diced before being ushered across the enterocyte through specialized pathways. After passage from the portal blood into the general circulation, folate is extracted by cell surface folate receptors, undergoes endocytosis, and is then shunted together with a proton across another channel into the cytoplasm. It is then received by an overabundance of high-affinity multifunctional enzymes that channel the folate across set pathways to support critical synthesis of thymidine for DNA and other key cellular functions including methylation reactions.

A general principle is that the preexisting store of these vitamins will dictate the speed with which overt deficiency develops; this is particularly relevant to pregnant women and children in resource-limited countries with preexisting borderline stores of folate and cobalamin.

The pathophysiology of cellular cobalamin and folate deficiency is most readily discerned by the clinician who approaches megaloblastosis with a clear understanding of the physiology of these vitamins. A detailed discussion of cobalamin and folate therefore follows.

COBALAMIN

The term *cobalamin* refers to a family of compounds with the structure shown in Fig. 40.1. Details of the chemistry, nomenclature, and in vivo substitutions of cobalamin are shown in Figs. 40.1–40.3, and excellent reviews are available on the colorful history, chemistry, and biology of cobalamin.[1–4]

Nutrition

Cobalamin is produced in nature only by microorganisms, and humans receive cobalamin solely from the diet.[5–8] Cobalamin is synthesized and used by some microorganisms (e.g., bacteria, fungi). Some strains (such as *Pseudomonas denitrificans*) produce cobalamin during fermentation, making them excellent and cheap commercial sources for cobalamin used in therapy. Herbivores obtain their dietary quota of cobalamin from plants contaminated with cobalamin-producing soil bacteria (rhizobia) that grow in roots and nodules of legumes. Because rhizobia-related organisms are also found in the large intestine of animals (and humans), volitional or inadvertent coprophagy can lead to intake of cobalamin by herbivores; however, cobalamin from manure that contaminates plants is not a significant source for humans.[5] Nevertheless, colonic cobalamin-producing bacteria—like *Klebsiella pneumoniae* that are related to rhizobia—can be found in the small intestine of some individuals from which cobalamin can be absorbed. For all practical purposes, there is *no* unfortified plant food, including fermented soy products, tempeh/*tempe*, seaweed (which are actually multicellular algae, such as nori [red algae], chlorella [green algae], spirulina [blue-green algae]), or other organic produce that can consistently provide a sufficient amount of active cobalamin to support daily requirements.

Animal protein is the major dietary cobalamin source for nonvegetarians. Meats from parenchymal organs are richest in cobalamin (over 10 μg/100 g wet weight); fish and muscle meats, milk products, and egg yolk have 1 to 10 μg/100 g of wet weight. An average nonvegetarian Western diet contains 5 to 7 μg/day of cobalamin, which adequately sustains normal cobalamin equilibrium. A vegetarian diet only supplies between 0.25 and 0.5 μg/day of cobalamin, so all vegetarians *do not* receive adequate dietary cobalamin and are at risk for cobalamin deficiency.[7–9] Even a Mediterranean diet with modest intake of animal-source proteins places mothers and babies at risk for cobalamin deficiency.[10] The current recommended daily allowance is 2.4 μg for men and nonpregnant women, 2.6 μg for pregnant women, 2.8 μg for lactating women, and 1.5 to 2 μg for children 9 to 18 years old.[11] However, reevaluation of cobalamin requirements

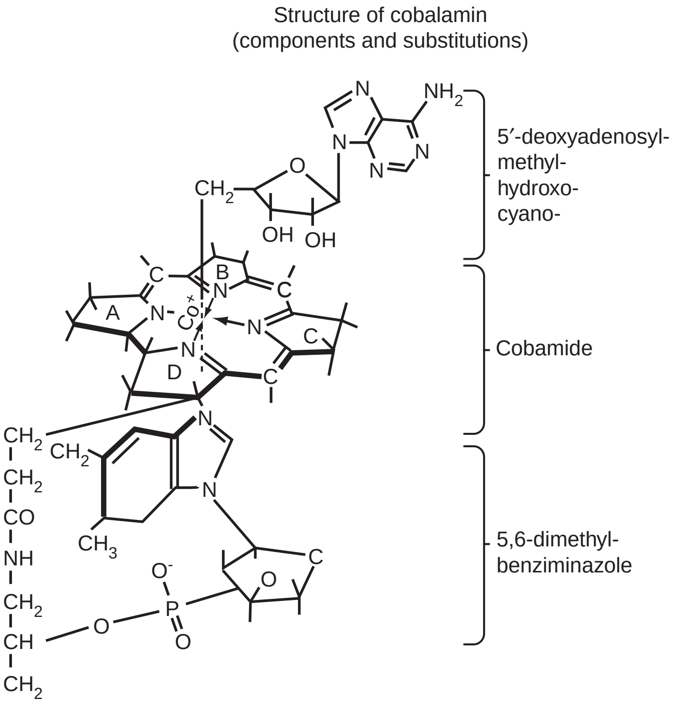

Figure 40.1 COBALAMIN (VITAMIN B_{12}) CHEMISTRY AND NOMENCLATURE. The central cobalt atom of cobalamin forms the focal point of this large complex organometallic molecule (approximately 1300 to 1500 Da). There are up to six ligands that can bind to this cobalt; of these, four involve nitrogen atoms of the planar corrin ring that surround the cobalt atom. The lower α-axial ligand, extending perpendicular below the corrin ring, links to nitrogen of a 5,6-dimethylbenzimidazole phosphoribosyl moiety that is also attached back to the corrin ring through one of its propionamide side chains (this is analogous to the hand guard on the handle on a saber that covers the knuckles of the hand). The upper or β-axial ligand varies and can exist in the fully oxidized Co^{3+} state, which is referred to as cob(III)alamin; in the Co^{2+} state, called cob(II)alamin (which can be used for the synthesis of methylcobalamin or adenosylcobalamin); or the fully reduced Co^{+} state (cob[I]alamin). These upper axial ligands include cyano- (cyanocobalamin), hydroxyl- (hydroxocobalamin), methyl- (methylcobalamin), or 5′-deoxyadenosyl- (adenosylcobalamin) and confer a distinct identity to cobalamin for participation in one-carbon metabolism. All these forms with substituted upper axial ligands are cob(III)alamins, which adopt a configuration in which the 5,6-dimethylbenzimidazole nitrogen base is coordinated to the cobalt in the lower axial position. This is referred to as the "base-on" position. However, when cobalamin is bound to the enzymes methionine synthase and methylmalonyl-CoA mutase, another conformational change results in the replacement of the 5,6-dimethylbenzimidazole by a histidine donated by the enzyme; this is the "His-on" position. Thus, shifts from "base-on/His-off" conformation to an alternative "base-off/His-on" conformation have an important bearing on the catalytic activity of these enzymes. Conversion of cyanocobalamin to its active cofactor forms requires a decyanation step. *(From Chanarin I. The Megaloblastic Anemias. Oxford, UK: Blackwell Scientific Publications; 1979.)*

within a university community (aged 18 to 50 years) from the USA suggests that a higher intake of 4 to 7 micrograms of cobalamin each day is optimum for adequate cobalamin status.[12] This is in line with earlier studies from the USA and Europe.[13–15]

Food cobalamin is stable to high-temperature cooking but is readily converted to inactive cobalamin analogues by ascorbic acid. Cobalamin is exceptionally well stored in tissues in its coenzyme forms. Of the total-body content of 2 to 5 mg in adults, about 1 mg is in the liver. There is an obligatory loss of 0.1% per day (1.3 μg) regardless of total-body cobalamin content. It takes about 3 to 4 years to deplete cobalamin stores when dietary cobalamin is abruptly malabsorbed, but it may take longer to develop nutritional cobalamin deficiency, because of an efficient enterohepatic circulation, which accounts for turnover of 5 to 10 μg/day of cobalamin.[16]

Absorption

Cobalamin in food is usually in coenzyme form (5′-deoxyadenosylcobalamin [adenosylcobalamin] and methylcobalamin), nonspecifically bound to proteins (see Fig. 40.2). In the stomach, peptic digestion at low pH is a prerequisite for cobalamin release from food protein.[16] Once released by proteolysis, cobalamin preferentially binds a high-affinity, 150-kDa, cobalamin-binding protein called *R protein* (a haptocorrin) from gastric juice and saliva that has an even higher affinity for cobalamin than gastric intrinsic factor (IF). The cobalamin-bound R protein complex (holo-R protein), along with excess unbound (apo)-R protein and IF, pass through into the second part of the duodenum, where pancreatic proteases degrade holo-R and apo-R proteins (but not IF). This results in the transfer of cobalamin to IF, a 45-kDa glycoprotein with high-affinity binding ($K_a = 1.5 \times 10^{10}\,M^{-1}$), 1 : 1 molar stoichiometry, stability, and resistance to proteolysis over a pH range of 3 to 9.[16] Failure to degrade holo-R proteins by pancreatic protease precludes the involvement of IF in cobalamin absorption because the downstream ileal IF-cobalamin receptors only interact with IF-bound cobalamin.[16] Although R proteins bind cobalamin and most cobalamin analogues with comparably high affinity, IF only binds cobalamin.

IF is produced in parietal (oxyntic) cells in the fundus and cardia of the stomach.[16] IF has two binding sites: one for cobalamin and another for the ileal IF-cobalamin receptor. IF is produced in far greater excess than is actually required for absorption; indeed, the IF in only 2 to 4 mL of normal gastric juice can reverse cobalamin deficiency in adults who lack IF.[16] In the absence of IF, less than 2% of ingested cobalamin is absorbed, whereas in its presence, approximately 70% is absorbed.

IF is secreted in response to food in the stomach in a manner analogous to secretion of acid (i.e., by vagal and hormonal stimulation). IF binds biliary cobalamin and newly ingested cobalamin following its transfer from R protein.[16] Because biliary cobalamin analogues are not transferred from R protein to IF, this is an efficient method for fecal excretion of cobalamin analogues while allowing for reabsorption of biliary cobalamin. The stable IF-cobalamin complex passes through the jejunum to the ileum, where specific membrane-associated IF-cobalamin receptors for IF-cobalamin are concentrated on microvilli of terminal ileal mucosal cells.[16]

The functional IF-cobalamin receptors are composed of a complex of two proteins collectively known as cubam, composed of *cub*ilin (CUBN)[17] and *am*nionless (AMN),[18] that is essential to complete transport of the IF-cobalamin complex from the intestinal lumen into the ileal enterocyte. CUBN is a large (400-kDa) peripheral membrane protein, which requires the smaller transmembrane protein, AMN, for its expression at the brush border, and vice versa. Dysfunction of cubam because of mutation in either CUBN or AMN is the basis for Imerslund-Gräsbeck syndrome. These IF-cobalamin receptors (cubam) require Ca^{2+} for binding at pH above 5.4; they do not bind free IF, cobalamin, or R protein–bound cobalamin; therefore these receptors are highly specific and have a high affinity for IF-cobalamin ($K_a = 1 \times 10^{9}\,M^{-1}$). The human ileum contains enough IF-cobalamin receptors [cubam] to bind up to 1 μg of IF-bound cobalamin; this is the rate-limiting factor in cobalamin absorption.[16]

After the cobalamin-IF complex is internalized by cubam for subsequent processing, these receptors are recycled back to the cell surface, whereas cobalamin enters the cytoplasm. Subsequent physiologic events are unclear. The multidrug resistance–associated protein (MRP) 1 mediates the cellular export of cobalamin across the basolateral membrane of intestinal epithelium.[19,20] Then cobalamin apparently binds transcobalamin II (TCII) within or at the basal surface of the ileal enterocyte.[16] TCII is abundant in the microvascular endothelium and cobalamin, which appears in portal blood largely (over 90%) bound to TCII, reaches peak levels in about 8 hours.[16]

Figure 40.2 COMPONENTS AND MECHANISM OF COBALAMIN ABSORPTION. *Cbl*, Cobalamin; *D. latum, Diphyllobothrium latum; HCl*, hydrochloric acid; *IF*, intrinsic factor; *R-Cbl*, R-protein bound cobalamin; *TCII*, transcobalamin II.

By contrast, therapeutically administered cobalamin in large doses can also passively diffuse through nasal, buccal, gastric, and jejunal mucosa so that less than 1% of a large dose of oral cobalamin appears in the circulation in minutes. This property is used to advantage in individuals with cobalamin malabsorption in lieu of parenteral replacement (discussed later).[16]

Transport

More than 90% of recently absorbed or injected cobalamin is bound to TCII, which is the specific serum transport protein for delivery of cobalamin to tissues. TCII, a 38-kDa polypeptide synthesized in many tissues, preferentially binds cobalamin with 1:1 molar stoichiometry and high affinity ($K_a = 1 \times 10^{11}\,M^{-1}$).[16] The TCII-cobalamin complex is rapidly cleared from the circulation in less than an hour. TCII-bound cobalamin binds to specific cell surface 58-kDa TCII-cobalamin receptors (encoded by the *CD320* gene) present on several cells.[21,22] High-affinity TCII-cobalamin binding to TCII-cobalamin receptors is specific only for holo- and apo-TCII ($K_a = \sim 5 \times 10^{10}\,M^{-1}$). However, because some cobalamin analogues can bind TCII with high affinity, these also have the same potential for cellular uptake as cobalamin.[16]

Circulating cobalamin, which is predominantly in the form of methylcobalamin, is not found free in plasma. Binding to TCII accounts for only 10% to 30% of the total serum cobalamin, with the majority (approximately 75%) of remaining cobalamin being bound to another protein, transcobalamin I (TCI). TCI (another haptocorrin) binds biologically active cobalamins as well as biologically inactive cobalamin derivatives. Because TCI is not a cellular transport protein, it is best viewed as a plasma-storage form of cobalamin; indeed, cobalamin-bound TCI has a slow clearance rate (half-life of 9 to 12 days).[23] A third transport protein, transcobalamin III (TCIII), is closely related to TCI but has a half-life in minutes because it is an asialoglycoprotein. TCIII binds a wide spectrum of cobalamin analogues with high affinity and delivers them via hepatic asialoglycoprotein receptors to hepatic cells, and thence into bile for fecal excretion. Between 0.5 and 9 µg of cobalamin taken up by hepatic TCII receptors is secreted into bile, of which approximately 75% is reabsorbed, analogous to food cobalamin,[16] reflecting an efficient enterohepatic circulation of cobalamin.

Cellular Processing

Once bound to TCII receptors, the TCII-cobalamin complex is internalized by conventional receptor-mediated endocytosis (see Fig. 40.3).[16] At the low pH extant in lysosomes, TCII dissociates from cobalamin and is degraded, whereas transport of cobalamin across lysosomes into the cytosol requires two distinct membrane proteins,

Figure 40.3 CELLULAR UPTAKE AND INTRACELLULAR REACTIONS INVOLVING COBALAMIN. A large family of natural and synthetic cobalamins can be generated when the cyanide (CN) moiety (upper axial ligand in cyanocobalamin) is replaced. On exposure to light, CN is gradually lost from cyanocobalamin, with the production of hydroxocobalamin. In vivo substitutions include the replacement of hydroxocobalamin or cyanocobalamin by a 5′-deoxyadenosyl group attached by a covalent bond, giving rise to adenosylcobalamin (AdoCbl). Methylcobalamin (MeCbl) is the main form in plasma. In vivo, 5-methyltetrahydrofolate readily donates its methyl group to cob(I)alamin in a reaction involving methionine synthase to form methylcobalamin. Transport of cobalamin across lysosomes requires two distinct membrane proteins, LMBRD1 and ABCD4, which act synergistically and, when lacking, give rise to cblF and cblJ complementation groups, respectively. The approximate loci for defects in cobalamin mutants, cblA to cblJ, are shown. See text for details. *MMCoA mutase*, Methylmalonyl-CoA mutase; *SAH, S*-adenosylhomocysteine; *SAM, S*-adenosylmethionine.

LMBRD1 and ABCD4, which act synergistically (see Fig. 40.3).[20] Cob(III)alamin, the most "oxidized" form of cobalamin, must be converted to cob(II)alamin and cob(I)alamin by two sequential reductase steps (see Fig. 40.3). Once in the cytoplasm, cobalamin is bound to CblC, an enzyme that catalyzes removal of the cyano or methyl or adenosyl groups that are bound to cobalt in the cobalamin molecule.[20,24] From here, cobalamin is moved to target enzymes in the mitochondria or the cytoplasm.

Over 95% of intracellular cobalamin is bound to two intracellular enzymes, methylmalonyl-CoA mutase and methionine synthase.[16] When cobalamin interacts with its target enzymes, it exists in a "base-off/His-on" conformation, which reflects a very close relationship with these enzymes (see legend for Fig. 40.1).

In mitochondria, cob(I)alamin is converted to its coenzyme form, adenosylcobalamin, which acts as a coenzyme with methylmalonyl-CoA mutase to mediate the intramolecular exchange of a hydrogen atom attached to one carbon atom with a group attached to an adjacent carbon atom; in this way, methylmalonyl-CoA is converted to succinyl-CoA (methylmalonyl-CoA is normally generated during the catabolism of branched-chain amino acids, odd-chain fatty acids, and cholesterol). When formed, succinyl-CoA can then enter the Krebs tricarboxylic acid cycle.

In the cytoplasm, cobalamin, as methylcobalamin, functions as a coenzyme for methionine synthase, a critical enzyme for which both folates and cobalamin are required for normal one-carbon metabolism (see Fig. 40.3). Methionine synthase is a modular protein with four distinct and separate regions for binding homocysteine, 5-methyltetrahydrofolate (5-methyl-THF; 5-methyl-H_4PteGlu), the cobalamin prosthetic group, and *S*-adenosylmethionine (SAM).[23] The reaction proceeds by methyl transfer from 5-methyl-tetrahydrofolate to methionine synthase–bound cob(I)alamin to form methylcobalamin, followed by transfer of this methyl group to homocysteine to form methionine and regeneration of cob(I)alamin. In this process, 5-methyl-tetrahydrofolate is converted to tetrahydrofolate, which is subsequently polyglutamylated by folyl polyglutamate synthase; this addition of multiple glutamic acid moieties to tetrahydrofolate facilitates both its retention within cells and participation in one-carbon metabolism. During this reaction, spontaneous oxidation of cob(I)alamin (which has no axial ligand) to the catalytically inactive cob(II)alamin form requires reduction back to cob(I)alamin before it can accept a methyl group. There is a specific redox regulator known as methionine synthase reductase that restores enzyme activity in the presence of SAM and NADPH[25]; this enzyme is mutated in patients with cblE mutations.

The physiologic importance of the key cofactor roles of the two forms of cobalamin (i.e., adenosylcobalamin and methylcobalamin) in methylmalonyl-CoA mutase and methionine synthase, respectively, is that the products and by-products of these enzymatic reactions are critical for DNA, RNA, and protein biosynthesis.

FOLATES

Nutrition

Folates (the anionic forms of folic acid, also called vitamin B_9) are synthesized by microorganisms and plants, including leafy vegetables (spinach, lettuce, broccoli), beans, fruits (bananas, melons, lemons), yeast, and mushrooms, and are also found in animal meats[8,16]; see Fig. 40.4 for chemistry and nomenclature. Among natural folates, which are predominantly in polyglutamylated form, only one-half are bioavailable; by contrast, 85% of folic acid that is added to food or ingested as a supplement is bioavailable. Several factors can influence the bioavailability of folates. These include: (1) The stability of the food folate. Natural reduced folates are labile and susceptible to oxidative cleavage by nitrates or light exposure, but folic acid is much more stable. Prolonged boiling or cooking over 30 minutes reduces natural folates by 50% to 80%, whereas ascorbate increases bioavailability, and refrigeration of leafy foods exposed to fluorescent light in supermarkets can double the folate content.[26] (2) Pureed foods allow easier access to the glutamate carboxypeptidase II (also known as folate-polyglutamate hydrolase), which converts folate polyglutamates to simpler folate monoglutamates to facilitate absorption[27]; so perturbation of this enzyme by organic acids (orange juice) or drugs (sulfasalazine, ethanol) can preclude absorption; conversely, high-affinity folate-binding proteins in human or cow's milk can increase folate absorption for infants and women, respectively.[28] (3) Interference with the proton-coupled folate transporter (PCFT)-mediated folate absorption across the proximal jejunum from either intestinal diseases or drugs (proton-pump inhibitors, sulfasalazine, pyrimethamine)[29,30] will affect the bioavailability of food folate.

The recommended daily allowance of folate is as follows: adult men and nonpregnant women, 400 µg; pregnant women, 600 µg; lactating women, 500 µg; children 9 to 18 years, between 300 and 400 µg.[31] A balanced Western diet contains adequate amounts of folate, but the net dietary intake of folate in many resource-limited countries is often insufficient to sustain folate balance.[8,16,32–34]

Absorption

After dietary folate polyglutamates are converted to folate monoglutamates at the enterocyte brush border, they are transported through the duodenal and jejunal brush border by physiological, high-affinity, luminal surface–facing membrane PCFTs, which are most efficient in an acidic milieu. At pH 5.5, there is equivalent affinity for transport of physiologic reduced folates and folic acid, but at pH 6.5, reduced

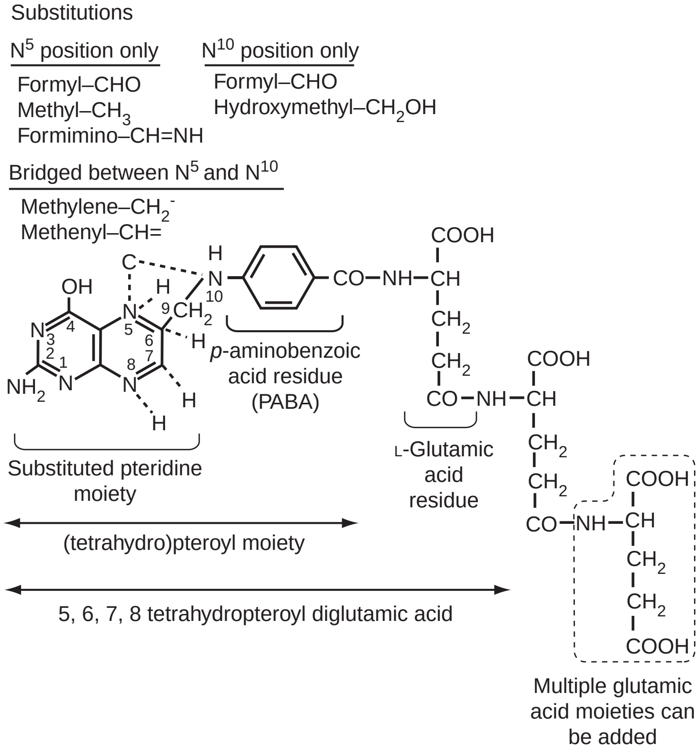

Figure 40.4 FOLATE CHEMISTRY AND NOMENCLATURE. Folic acid (pteroylmonoglutamate [PteGlu]) is the commercially available parent compound for more than 100 compounds collectively referred to as *folates*. PteGlu consists of three basic components: a pteridine derivative, a *p*-aminobenzoic acid residue, and an L-glutamic acid residue. Before PteGlu can play a role as a coenzyme, it must first be reduced at positions 7 and 8 to dihydrofolic acid (H_2PteGlu) and then to 5,6,7,8-tetrahydrofolic acid (THF; H_4PteGlu), and one to six additional glutamic acid residues must then be added by means of γ-peptide bonds to the L-glutamate moiety (for which the subscripted *n* in PteGlu_n denotes polyglutamation). Folate coenzymes donate or accept one-carbon units in numerous reactions in amino acid and nucleotide metabolism. The various substitutions in $H_4\text{PteGlu}_n$ occur at positions 5 or 10, or both; position 5 can be substituted by methyl (CH_3), formyl (CHO), or formimino (CHNH), and position 10 can be substituted by formyl or hydroxymethyl (CH_2OH). Positions 5 and 10 can be bridged by methylene ($–CH_2–$) or methenyl (–CH=). For an engaging account of the history of folic acid, see the article by Hoffbrand and Weir.[311]

5-methyl-tetrahydrofolate is transported more efficiently.[35] PCFT is a folate-hydrogen symporter, so with each folate molecule transported, there is a net translocation of positive charge. Loss-of-function mutations in PCFT in the enterocyte and choroid plexus result in hereditary folate malabsorption,[29,36] where there is an inability to transport folate across the intestine and the choroid plexus. Within the enterocyte, folates are reduced to tetrahydrofolate and then methylated before release into plasma as 5-methyl-tetrahydrofolate. Most of the folic acid taken up by the PCFT in the proximal small intestine is also converted within the enterocyte to 5-methyl-tetrahydrofolate. Folate production by bacteria in the small intestine can also enter the circulation.[37]

The flux of folate from the basolateral membrane of the enterocyte to the portal blood is mediated through MRP3.[29] MRP proteins have low affinity but high capacity and are best viewed as cellular "sump pumps" that eject excess folates (and antifolates) out of cells. Together with MRP2, which mediates folate transport into bile,[38] these MRPs maintain an efficient enterohepatic circulation, which helps retain folate.[29]

Some bacterially produced folates, especially those produced by probiotic bacteria (genus *Bifidobacterium*), can be absorbed across the large intestine,[39] sufficient to raise the serum folate levels,[40] but normally this accounts for no more than about 5% of the average folate requirement.

Passive diffusion of folic acid (which is formally referred to as pteroylmonoglutamate [and abbreviated as PteGlu]) is probably the primary mechanism of intestinal mucosal folate absorption at high pharmacologic concentrations.[16] The small intestine has a large capacity to absorb folate, with peak folate levels in plasma achieved 1 to 2 hours after oral administration.

Plasma Transport and Enterohepatic Circulation

The normal serum folate level is maintained by dietary folate and a substantial enterohepatic circulation that amounts to about 90 μg/day of folate.[16] Biliary drainage results in a dramatic fall in serum folate (to about 30% of basal levels in 6 hours), whereas abrupt interruption of dietary folate leads to a fall in serum folate levels in about 3 weeks. In the plasma, one-third of the folate is free, two-thirds are nonspecifically bound to serum proteins, and a small fraction binds soluble folate receptors. In contrast to cobalamin uptake, there is no specific *serum* transport protein that enhances cellular folate uptake.

Cellular Folate Uptake

Folate Receptors

Plasma 5-methyl-tetrahydrofolate and folic acid are rapidly transported into proliferating cells by specialized, high-affinity, glycosylphosphatidylinositol-anchored (membrane) folate receptor-α, which takes up these folates at physiologic (nanomolar) concentrations in serum.[41–43] The plasma membrane containing the folate–folate receptor complex then invaginates and forms an endosomal vesicle that moves into the cytoplasm along microtubules.[44] The perinuclear endosomal compartment then gets acidified to pH 6, which dissociates folate from folate receptors. The released folate then passes across the acidified endosome into the cytoplasm by a transendosomal pH gradient, which is mediated by either the PCFT, which closely colocalized with folate receptors, or a related moiety (Fig. 40.5).[36,45]

Folate receptor-α is critical to mediating the cellular uptake of folates in proliferating normal and malignant cells, in transport of folate across the placenta to the fetus,[42,46] across the choroid plexus into the brain,[47–49] and in renal conservation of folates.[45,50] Folate receptor-α is expressed in several types of cancer cells, whereas folate receptor-β is expressed most in monocytes and macrophages[51–53]; hence these two forms of folate receptors are under investigation for potential clinical use in detecting (and treating) occult malignancy and inflammation, respectively.[51–55]

The physiologic role of reduced-folate carriers is less clear; it is a low-affinity but high-capacity system that can also mediate the uptake of 5-methyl-tetrahydrofolate and pharmacologic folates (like methotrexate and folinic acid well, but folic acid poorly) into a variety of cells at physiologic pH.[36,45] Induction of the upregulation of reduced-folate carriers via the blood-brain barrier is being investigated as a means to improve folate transport into the brain when there is either hereditary or acquired perturbation of the physiological components of brain folate transport (folate receptors and PCFT).[56]

Folate Receptor Regulation and Cellular Folate Homeostasis

Cell surface folate receptor-α is upregulated in response to low extracellular and intracellular folate concentrations through transcriptional, translational, and posttranslational mechanisms.[57–62] During cellular folate deficiency the accumulation of intracellular homocysteine leads to its covalent binding to a cytoplasmic protein known as heterogeneous nuclear ribonucleoprotein-E1 (hnRNP-E1), which mediates translational upregulation of folate receptor-α.[58,63] Homocysteinylation of hnRNP-E1 at specific cysteine–cysteine disulfide bonds leads to the unmasking of an underlying messenger RNA (mRNA)-binding pocket for which folate receptor-α mRNA has a high affinity. This RNA-protein interaction then triggers the biosynthesis of folate receptors, which can then bind available folate and normalize cellular folate levels; in turn, this reduces the intracellular homocysteine concentration to baseline.[62] In this context, hnRNP-E1 fulfills criteria as a cellular sensor of physiologic folate deficiency (Fig. 40.6) because this protein is able to sense folate deficiency by interacting with homocysteine—a sensitive indicator of folate deficiency—and then respond by increasing RNA-protein interaction that triggers the biosynthesis and upregulation of folate receptors and restores folate status to normal.[62,64]

The broader significance of this mechanism is that *homocysteinylated hnRNP-E1 actually orchestrates a nutrition-sensitive posttranscriptional RNA operon during folate deficiency*. This is because the unmasked mRNA-binding pocket within homocysteinylated-hnRNP-E1, which is highly promiscuous, allows for binding of a variety of very diverse mRNAs (perhaps over 100), all of which have a common password composed of short RNA sequences; these RNA-protein interactions can, in turn, trigger the modulation (up or down) of a variety of several otherwise entirely unrelated proteins that likely contribute to the biologic features of reduced cell proliferation, differentiation, and apoptosis, which are a hallmark of folate deficiency.[62,65]

In the nucleus, folate receptors can also function as a transcription factor by binding to cis-regulatory elements at promoter regions of *Fgfr4* and *Hes1* to regulate their expression.[66]

Folate Receptors and Placental Folate Transport

Human placental folate receptors[67,68] that are abundant and polarized only on the maternal-facing microvillous membrane of the syncytiotrophoblast[69] are critical to transplacental maternal-to-fetal folate transport.[46] Physiologic transplacental folate transport relies on the continued provision of adequate dietary folate intake by the mother. Following capture of maternal folate by placental folate receptors,[43,70] the displacement of this pool by incoming dietary folates results in an intervillous blood concentration that is three times that of maternal blood. This allows for subsequent transfer of the folate to the fetal circulation along a downhill concentration gradient[46] and ensures continued unidirectional transplacental folate transport. Thus a suboptimum intake of folate by the mother can reduce maternal-to-fetal folate transfer and predispose the embryo/fetus to serious developmental defects.[71–73]

Because PCFT colocalizes with folate receptor-α, it is suggested that following binding and internalization of folate into low-pH endosomes, the folate dissociates from folate receptors and presumably passes via PCFT into the cytoplasm. However, because

both PCFT and reduced-folate carriers are uniformly distributed in microvillous membrane, cytoplasm, and the fetal-facing basal plasma membrane,[69] the following events are all still unclear in human transplacental folate transport to the fetus: the precise handover of folate following endocytosis into the cytoplasm, the potential role of transcytosis of vesicles containing folate, the transport of folate across the syncytiotrophoblast basement membrane into the fetal vasculature, and the role of MRPs.

Folate Receptors in Embryonic and Fetal Development

Folate receptor-α is among the earliest genes activated in embryonic stem cells[74] when there is the need for increased folate requirements to support DNA synthesis during spectacular bursts of intense cell proliferation—ranging as short as 2 to 3 hours during brief windows within the proliferative zone in the epiblast.[16,72] Thus maternal folate deficiency compromises embryonic and fetal development—and probably even accounts for early miscarriages, as suggested by experimental studies in mice.[60]

Both early-stage neural tube cells and neural crest cells abundantly express folate receptor-α. Experimental perturbation of folate receptor-α[60,71,73,75–77] can lead to profound abnormalities in neural-tube closure leading to neural-tube defects (NTDs), as well as in heart, facial, and eye development which are collectively referred to as neurocristopathies. These neurocristopathies derive from abnormal proliferation and/or migration and/or differentiation of neural crest cells and result in cleft lip or cleft palate, endocardial cushion defects, and other midline defects.[71–73] Such studies are consistent with a physiologic role for folate receptor-α and the importance of its functioning normally to prevent the development of NTDs and neurocristopathies. Thus congenital heart defects, comprising approximately 1% of live births, and NTDs, among the most common congenital neurologic birth defects, are both dependent on the fidelity of folate receptor-α expression, precisely at the right time and in the right cells during early cardiac and neurologic development. The finding of a significant increase in blocking autoantibodies against placental

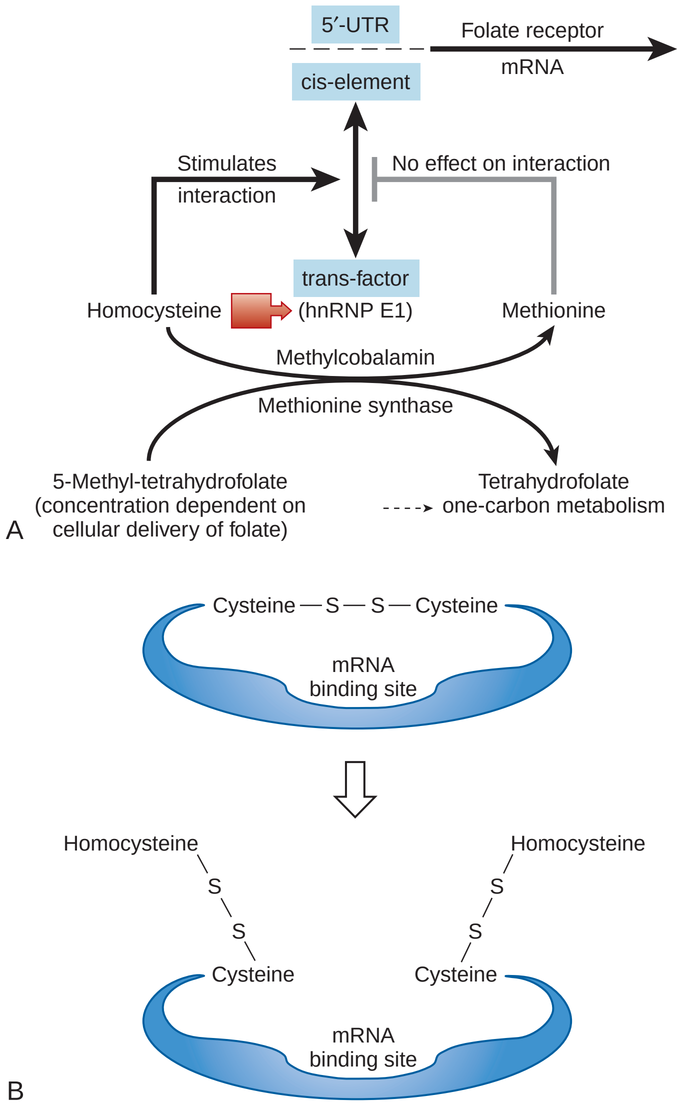

Figure 40.6 MODEL FOR HOW THE CELL SENSES FOLATE DEFICIENCY AND RESPONDS BY UPREGULATING FOLATE RECEPTORS. This model links perturbed folate metabolism, ribonucleic acid (RNA)–protein interaction, and coordinated translational regulation of folate receptors to optimize cellular folate uptake and restore folate homeostasis. The prominent *red arrow* highlights the critical role of heterogeneous nuclear ribonucleoprotein E1 (hnRNP-E1) as a sensor of cellular folate deficiency. (A) Reduced folate availability results in inactivation of methionine synthase and intracellular homocysteine build-up, which induces a direct posttranslational *S*-homocysteinylation of hnRNP-E1 via targeted homocysteine-*S-S*-cysteine mixed disulfide bonds; this results in the unmasking of a high-affinity folate receptor messenger RNA (mRNA) cis-element binding site and the RNA-protein interaction leads to increased translation of folate receptor-α. The net effect is a homeostatic response that aims to restore intracellular folate concentrations to normal by upregulating cell surface folate receptor. Folate repletion reactivates methionine synthase, which converts homocysteine to methionine, which has no effect on the RNA–protein interaction. As a result, the reduction in cellular homocysteine leads to reduced folate receptor-α synthesis and its downregulation. (Note: other metabolic pathways involving homocysteine are not included.) (B) A proposed mechanism for the unmasking of a cryptic mRNA binding site in hnRNP-E1 following the covalent binding of L-homocysteine, through the replacement of one (of many potential) cysteine disulfide bonds by protein-cysteine-*S-S*-homocysteine mixed disulfide bonds. *5′-UTR*, 5′ Untranslated region. *(From Tang YS, Khan RA, Zhang Y, et al. Incrimination of heterogeneous nuclear ribonucleoprotein E1 (hnRNP-E1) as a candidate sensor of physiological folate deficiency. J Biol Chem. 2011;286:39100.)*

folate receptor-α in women with pregnancy complicated by NTDs[78] is a striking human correlate of experimental studies in mice using antibodies, but the causal relationship warrants additional study.[76] Folate receptor-α also provides folate during neuronal regeneration and repair after injury where DNA methylation is also involved.[79]

Folate Receptors and Proton-Coupled Folate Transporter in Cerebral Folate Transport Across the Choroid Plexus

The pathway of folate receptor–α dependent basolateral-to-apical transcytosis within vesicles across the choroid plexus cells followed by exosome-mediated folate delivery across the cerebrospinal fluid (CSF) into the brain parenchyma has been characterized.[47] Briefly, 5-methyl-THF is bound by glycosyl-phosphatidyl inositol (GPI)-anchored folate receptor-α on the basolateral surface of choroid plexus cells. Following endocytosis there is sequential transfer of folate receptor-α-bound folate from an early- to a later-endosomal compartment called multivesicular bodies. The inward budding of the limiting membrane of multivesicular bodies leads to formation of several intraluminal vesicles that now contain outward-facing folate receptor-α. Following transcytosis of multivesicular bodies (containing their cargo of intraluminal vesicles) and eventual fusion with the apical membrane, there is discharge of these intraluminal vesicles as 40 to 100 nm exosomes into the CSF. These exosomes (containing outward oriented folate receptor-α-bound folates) then cross the ependymal cell layer and enter the brain parenchyma.[47]

Some of the endocytosed folate receptor-α-bound folate is transported out of acidified endosomal compartments via PCFTs into the choroid plexus cell cytoplasm.[47] However, more information on the cooperative function of folate receptor-α and PCFT in folate transport to the human brain is required, particularly because loss of PCFT-mediated function in hereditary folate malabsorption profoundly compromises choroid plexus transport of folates.[36,80]

Renal Retention of Folates (and Cobalamin)

After glomerular filtration, luminal folate binds folate receptor-α in the brush border membranes of proximal renal tubular cells and is internalized rapidly by folate receptor-α–mediated endocytosis; in the low pH of endocytotic vesicles, there is dissociation of folates and slow transport across basolateral membranes into the blood, with recycling of apo-folate receptor-α back to the luminal brush border membrane.[42,44] A large 550-kDa membrane protein called megalin, which interacts with CUBN and is found in renal proximal epithelial cells, functions as a multiligand receptor for a variety of macromolecules.[81,82] Megalin also binds to and mediates endocytosis of TCII-cobalamin complexes as well as filtered folate bound to soluble folate-binding proteins in kidney proximal tubules.[83]

INTRACELLULAR ONE-CARBON METABOLISM AND COBALAMIN–FOLATE RELATIONSHIPS

Cellular Folate Retention and One-Carbon Metabolism

Polyglutamylation of folate by the enzyme folylpolyglutamate synthase catalyzes the addition of multiple glutamate equivalents to their γ-carboxyl residue (see Fig. 40.4 and 40.5). In most eukaryotic cells, the pentaglutamate and hexaglutamate forms predominate. Polyglutamylation retains folates within cells; in addition, polyglutamylated folates are more efficient substrates for folate-dependent enzymes. In human erythrocytes (red blood cells [RBCs]), folate is accumulated at earlier stages within the marrow by folate receptors[84,85]; on maturation, more than 90% of $H_4PteGlu_{(n)}$ molecules interact with hemoglobin, which, because of its high capacity, assists in intracellular folate retention.[16]

Compartmentalization and Channeling of Folate Metabolism

In an elegant example of conservation of resources, metabolic pathways involving folate are compartmentalized within cells as multienzyme complexes that shuttle one-carbon units along set paths toward key reactions leading to pyrimidine and purine biosynthesis. The major form of folate transported into the cell is 5-methyl-tetrahydrofolate (5-methyl-THF; 5-methy-H_4PteGlu) (see Fig. 40.5); by contrast, folic acid (pteroylmonoglutamate (PteGlu) requires reduction to tetrahydrofolate by dihydrofolate reductase in a two-step reaction (PteGlu to *dihydro*pteroylglutamate [H_2PteGlu] to *tetrahydro*pteroylglutamate [H_4PteGlu, or THF]). After cellular uptake, 5-methyl-THF must first be converted to THF via methionine synthase (in the methylation cycle). This is a key reaction because THF is the preferred physiologic substrate for folylpolyglutamate synthase, which adds multiple glutamate moieties to THF (see Fig. 40.4). Only then can the polyglutamylated form of THF participate in one-carbon metabolism where it can be converted to either 10-formyl-THF—used in de novo biosynthesis of purines—or to 5,10-methylene-THF—used for synthesis of thymidylate. Moreover, 5,10-methylene-THF and 10-formyl-THF can be interconverted by intermediates (see Fig. 40.5).

Folate metabolism and folate-dependent enzymes are compartmentalized: approximately 40% are in the mitochondrial matrix, 50% in the cytoplasm, and 10% in the nucleus.[86] The methylation reaction occurs in the cytosol whereas thymidylate synthesis occurs in the nucleus. The mitochondrial compartment, which is *not* shown in Fig. 40.5, contains its complement of folate cofactors, and homologues of the major cytosolic enzymes. For example, cytoplasmic 5-methyl-THF and 5-formyl-THF can enter mitochondria by a mitochondria-specific reduced-folate carrier,[87] whereas SAM, which is also required for mitochondrial methylation reactions, enters mitochondria by a specific transporter.[88] Other one-carbon donors like serine, glycine, dimethylglycine, and sarcosine also enter mitochondria and ultimately generate formate that crosses back into the cytoplasm. In the cytoplasm, C1-THF synthase, a trifunctional enzyme, uses this mitochondria-derived formate with THF to form 10-formyl-THF, which is required for the de novo synthesis of purines (see Fig. 40.5); this enzyme can also catalyze the interconversion of THF, 10-formyl-THF, 5,10-methenyl-THF, and 5,10-methylene-THF. In this way, the continued delivery of mitochondrial formate helps perpetuate cytoplasmic one-carbon metabolism.[86] Another major entry point of one-carbon units into cytoplasmic folate metabolism is through the formation of 5,10-methylene-THF from serine (which is derived from glycolytic intermediates); here the enzyme serine hydroxymethyltransferase catalyzes the addition of carbon 3 from serine to THF to give rise to the key intermediate coenzyme 5,10-methylene-THF.[86] After 5,10-methylene-THF is converted to 5-methyl-THF by the enzyme methylenetetrahydrofolate reductase, it can be used in the methylation cycle, which involves methylation of homocysteine via methionine synthase to form methionine and tetrahydrofolate. After 5,10-methylene-THF is converted (via intermediates) to 10-formyl-THF, it can be used for purine nucleotide biosynthesis involving de novo synthesis of purine nucleotides for DNA and RNA. 5,10-Methylene-THF can also be used in the thymidylate cycle via the enzyme thymidylate synthase, which generates thymidylate (by converting deoxyuridine monophosphate [dUMP] to deoxythymidine monophosphate [dTMP]) for DNA synthesis (see Fig. 40.5). Parenthetically, this nuclear one-carbon metabolism compartment is activated during S phase of the cell cycle, following a posttranslational modification of folate-dependent enzymes like thymidylate synthase, serine-hydroxymethyltransferase, and dihydrofolate reductase by specialized small ubiquitin-like modifier (or SUMO) proteins; this modification allows the entry and enrichment of these sumoylated enzymes into the nucleus[89] to provide a buffer against the stress of imminent folate deficiency.[90]

Methylation

After methionine is generated, it can be converted to a methyl donor through its adenosylation to SAM. SAM is a universal donor of methyl groups for critically important biologic methylation reactions involving over 80 proteins, membrane phospholipids, the synthesis of neurotransmitters, RNA, DNA, and histones. Among these, DNA methylation is a major epigenetic mechanism that is central to the regulation of several cellular functions such as gene transcription, chromatin structure, imprinting, development, and genomic instability. DNA is highly methylated in CpG sequences (over 50%); here a methyl group is targeted to the DNA base cytosine in the context of a CpG dinucleotide by DNA methyltransferases. Methylation confers a condensed structure and transcriptional repression, whereas hypomethylation does the opposite. Altered patterns of DNA methylation, particularly hypomethylation involving growth-promoting genes, or hypermethylation of tumor suppressor genes, are popular contemporary themes in our understanding of the epigenetic changes in DNA and the genesis of cancer. In addition, histone hypomethylation can alter gene expression. After these transmethylation reactions that use SAM, the immediate product of these reactions is *S*-adenosylhomocysteine (SAH), which is converted to homocysteine by SAH hydrolase. The SAM to SAH ratio regulates the balance of such cellular methylation reactions.

Dietary folate deficiency can lead to hypomethylation in animals, whereas folate consumption supports normal patterns of methylation. However, analysis in humans has not yielded consistent results, nor has the correlation of folate status and DNA methylation been sufficiently rigorously studied.

Consequences of Perturbed One-Carbon Metabolism

Methyl-Folate Trapping

Because of the critical role of methylcobalamin for methionine synthase, a deficiency of cobalamin inactivates methionine synthase and results in the accumulation of the substrate 5-methyl-THF; this so-called methyl-folate trap results because the upstream enzyme reaction involving methylenetetrahydrofolate reductase (which converts 5,10-methylene THF to 5-methyl-THF in preparation for the methionine synthase reaction) is also irreversible. Therefore when 5-methyl-THF accumulates and cannot be converted to THF, it readily leaks out of the cell. (This explains why patients with cobalamin deficiency can have normal to high serum folate values even in the face of tissue folate deficiency). The ensuing intracellular THF deficiency compromises one-carbon metabolism and initiates the pathophysiologic cascade leading to perturbed DNA synthesis and megaloblastosis.

Thymidylate Deficiency and Perturbed DNA Synthesis

With either cobalamin or folate deficiency, there will be a net decrease in 5,10-methylene-THF that interrupts the thymidylate synthase–mediated conversion of dUMP to dTMP. (Although salvage pathways for purine synthesis can compensate for reduced generation of purines through one-carbon metabolism, salvage pathways cannot compensate for reduced thymidine.) This results in a high dUMP/dTMP ratio and an increase in deoxyuridine triphosphate (dUTP), which can get misincorporated into DNA. At this juncture, an editorial enzyme recognizes this faulty misincorporation and excises dUTP. However, with a continued inadequate supply of deoxythymidine triphosphate (dTTP) there is a continued cycle of uracil misincorporation into DNA in folate deficiency,[91–93] its removal by uracil-DNA glycosylase,[93] and refilling of the missing base by DNA polymerase β.[94] However, with repetition over several cycles, multiple single-strand nicks are introduced into DNA; this predisposes to chromosome breaks[95] that can contribute to an increased risk of cancer associated with folate deficiency.[92,96,97] In addition, folate deficiency can also lead to double-strand breaks in DNA, which are difficult to repair when the two nicks are close to one another (within 12 bp of each other) on opposite strands.[98] Collectively, such double-strand DNA breaks in folate-deficient cells predispose to the development of acentric chromosomes, DNA fragments, and micronuclei.[95,99] This can also render folate-deficient epithelial tissues more permissive to the genomic integration of HPV16 DNA, and trigger HPV16-induced cancer.[100,101]

Chromosome and Cell Cycle Defects

Defective DNA synthesis caused by folate deficiency is reflected by numerous chromosomal abnormalities, including abnormalities in telomeres, which correlate with biomarkers of chromosomal instability and mitotic dysfunction.[102] There is excessive chromosomal elongation with despiralization associated with random breaks and exaggerated centromere constriction, expression of folate-sensitive fragile sites in hematopoietic cells, and reduced biosynthesis, acetylation, and methylation of arginine-rich histone.[23] All this leads to perturbation of the cell cycle with an increased proportion of cells in prophase of the mitotic cycle and G_2 that leads to apoptosis of erythroid precursors and anemia.[23]

MORPHOLOGIC EXPRESSION OF MEGALOBLASTOSIS

There is widening disparity in nuclear-cytoplasmic asynchrony as a cobalamin- or folate-deficient cell divides, until the more mature generations of daughter cells die in the marrow or are arrested (as megaloblastic cells) at various stages of the cell cycle.[16] All proliferating cells exhibit megaloblastosis, including the luminal epithelial mucosal cells of the entire gastrointestinal tract, cervix, vagina, and uterus.[16] However, megaloblastic changes are most striking in the blood and bone marrow. Ineffective hematopoiesis extends into long bones, and the bone marrow aspirate—which is superior to the biopsy for observing megaloblastosis—exhibits trilineal hypercellularity, especially of the erythroid series. Indeed, the plethora of bone marrow morphologic changes can lead an untrained observer to the diagnosis of erythroleukemia. The appearance of exuberant cell proliferation with numerous mitotic figures is misleading because these cells are actually proliferating very slowly (see box on Morphology in Megaloblastosis From Cobalamin and Folate Deficiency).

Erythroid hyperplasia reduces the myeloid-to-erythroid ratio from 3:1 to 1:1. Proerythroblasts are not as obviously abnormal as later forms; they may simply be larger (promegaloblasts). Megaloblastic changes are most strikingly displayed in intermediate and orthochromatic stages, which are larger than their normoblastic counterparts. In contrast to the normally dense chromatin of comparable normoblasts, megaloblastic erythroid precursors have an open, finely stippled, reticular, and sieve-like pattern (Fig. 40.7). The orthochromatic megaloblast, with its hemoglobinized cytoplasm, continues to retain its large sieve-like immature nucleus, in sharp contrast to the clumped chromatin of orthochromatic normoblasts. The nucleus is often eccentrically placed in these large oval or oblong cells, and lobulation or indentation of nuclei with bizarre karyorrhexis is often seen. In cells destined for the circulation as macro-ovalocytes, the nucleus may occasionally not be completely extruded. Of the potential progeny of proerythroblasts that develop into later megaloblastic forms, 80% to 90% die in the bone marrow. Marrow macrophages effectively scavenge dead or partially disintegrated megaloblasts. This is the basis for ineffective erythropoiesis (intramedullary hemolysis).

Leukopoiesis is also abnormal. There is an absolute increase in these cells, which are large and have similar sieve-like chromatin. Spectacular giant (20 to 30 µm) metamyelocytes and “band” forms that are often seen are pathognomonic for megaloblastosis (see Fig. 40.7). There may be bizarre nucleoli with small cytoplasmic vacuoles. It is probable that giant metamyelocytes cannot easily traverse marrow sinuses, and their maturation into circulating hypersegmented polymorphonuclear neutrophils (PMNs) is unlikely. Granulation of the cytoplasm remains unaffected.

Megakaryocytes may be normal or increased in numbers and may exhibit additional complexities in megaloblastic expression (see Fig. 40.7). Complex hypersegmentation (i.e., pseudohyperdiploidy) is associated with liberation of fragments of cytoplasm and giant platelets into the circulation. The net output of platelets is decreased in severe megaloblastosis, and abnormal but reversible platelet dysfunction has been documented.[23]

In early cobalamin or folate deficiency, normoblasts may dominate the marrow with only a few megaloblasts seen. Complete transformation to megaloblastic hematopoiesis is observed in florid cases and is reflected by various degrees of pancytopenia.

The earliest manifestation of megaloblastosis is an increase in mean corpuscular volume (MCV) with macro-ovalocytes (up to 14 µm) (see Fig. 40.7). Because these cells have adequate hemoglobin, the central pallor, which normally occupies about one-third of the cell, is decreased. By contrast, thin macrocytes have larger than normal central pallor (Table 40.1). In severe anemia, poikilocytosis and anisocytosis are evident. Cells containing remnants of DNA (i.e., Howell-Jolly bodies), arginine-rich histone, and nonhemoglobin iron (i.e., Cabot rings) may be observed. Extramedullary megaloblastic hematopoiesis may also result in a leukoerythroblastic picture.

Nuclear hypersegmentation of DNA in PMNs strongly suggests megaloblastosis when associated with macro-ovalocytosis (see Fig. 40.7). Normally fewer than 5% of PMNs have more than five lobes, and no cells have more than six lobes in the peripheral blood; megaloblastosis is suggested when greater than 5% PMNs have more than five lobes or 1% PMN have more than six lobes. (See box on Diagnostic Issues: Information From the Peripheral Smear and Bone Marrow Aspirate.)

Ineffective use of iron results in an increased percentage of saturation of transferrin and increased iron stores. If there is associated iron deficiency, the MCV may be normal, and only iron therapy can unmask the megaloblastic manifestations in the peripheral blood. In thalassemia, the entire erythrocyte morphology normally expected in megaloblastosis is masked[16]; however, megaloblastic leukopoiesis is still observed. Significant intramedullary hemolysis (ineffective erythropoiesis) involving more than 90% of megaloblastic precursors is reflected by a lowered absolute reticulocyte count, increased bilirubin (up to 2 mg/dL), decreased haptoglobin, and increased lactate dehydrogenase (LDH) often above 1000 units/mL. There is also a modest decrease in the circulating RBC life span. (See box on Masked Megaloblastosis.)

Megaloblastosis in rapidly proliferating cells of the gastrointestinal tract leads to a variable degree of morphologic changes and atrophy of luminal epithelial cells. This leads to functional defects, which can include malabsorption of cobalamin and folate in some patients. A

MORPHOLOGY IN MEGALOBLASTOSIS FROM COBALAMIN AND FOLATE DEFICIENCY IS THE SAME

Peripheral Smear

- Increased mean corpuscular volume (MCV) with macro-ovalocytes (up to 14 µm), which is variously associated with anisocytosis and poikilocytosis
- Nuclear hypersegmentation of polymorphonuclear neutrophils (PMNs) (1% PMN with six lobes or 5% with five lobes)
- Thrombocytopenia (mild to moderate)
- Leukoerythroblastic morphology (from extramedullary hematopoiesis)

Bone Marrow Aspirate

- General increase in cellularity of all three major hematopoietic elements
- Abnormal erythropoiesis—orthochromatic megaloblasts
- Abnormal leukopoiesis—giant metamyelocytes and “band” forms (pathognomonic), hypersegmented PMNs
- Abnormal megakaryocytopoiesis—pseudo hyperdiploidy

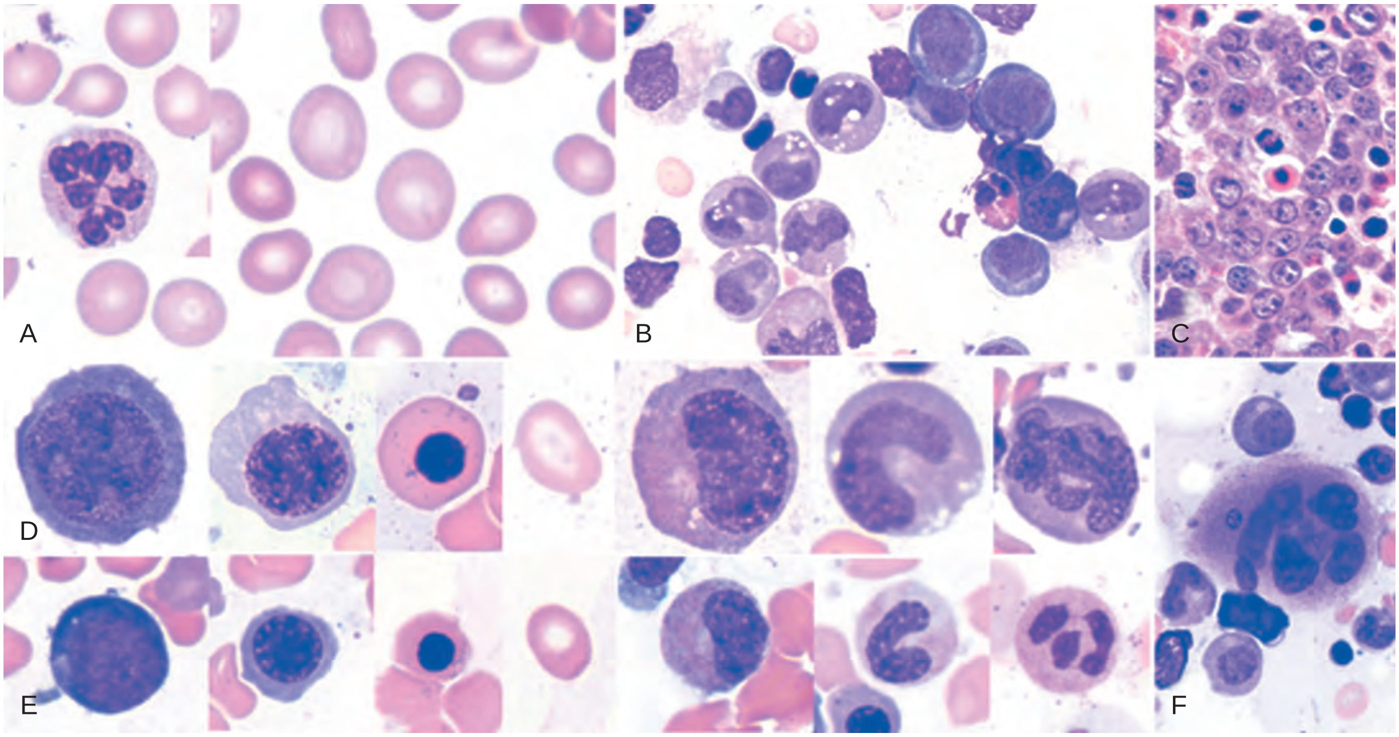

Figure 40.7 MEGALOBLASTIC ANEMIA. The peripheral smear (A) exhibits macro-ovalocytosis and a hypersegmented polymorphonuclear leukocyte *(inset)*. The bone marrow aspirate (B) shows megaloblastic changes in both granulopoiesis and erythropoiesis. The biopsy (C) is hypercellular and shows sheets of immature erythroid precursors with the appearance of a high mitotic rate. These can mimic acute erythroleukemia or even metastatic tumor cells. Details from the cells in the aspirate (D) compared with normal hematopoiesis at same magnification (E). Note the giant metamyelocyte and band form. In megaloblastic anemia, megakaryocytes also have nuclear atypia, including abnormal nuclear segmentation (F). Thus, the bone marrow aspiration and biopsy should be assessed for morphology, special stains, flow cytometry, and cytogenetic analysis. If the marrow is not obviously megaloblastic but the iron stain reveals absent stores, review the morphologic evaluation again with special emphasis on granulocytic precursors and promegaloblasts, and look for more subtle megaloblastic changes.

TABLE 40.1 Clinical Conditions Not to Be Confused With Megaloblastosis

Macrocytosis[a] Without Megaloblastosis[b]
Reticulocytosis
Liver disease
Aplastic anemia
Myelodysplastic syndromes (especially 5q–)
Multiple myeloma
Hypoxemia
Smokers
Spurious Increases in MCV Without Macro-Ovalocytosis[c]
Cold agglutinin disease
Marked hyperglycemia
Leukocytosis
Older individuals

[a] The central pallor that normally occupies about one-third of the normal red blood cell is decreased in macro-ovalocytes. This contrasts with the finding of thin macrocytes, in which the central pallor is increased.

[b] Although megaloblastosis implies that a bone marrow test has been performed, with the addition of highly sensitive tests for the specific diagnosis of cobalamin and folate deficiency, the need for a bone marrow test is often dictated by the urgency to make the diagnosis.

[c] When the Coulter counter readings of a high MCV are not confirmed by looking at the peripheral smear.

MCV, Mean corpuscular volume.

vicious cycle whereby megaloblastosis begets more megaloblastosis is established that can be interrupted only by specific therapy with cobalamin or folate.

NEUROLOGIC DYSFUNCTION WITH COBALAMIN DEFICIENCY

Because megaloblastosis caused by folate or cobalamin deficiency leads to a functional folate coenzyme deficiency, the morphologic manifestations of both deficiencies are understandably indistinguishable. However, only cobalamin deficiency results in a patchy demyelination process, which is expressed clinically as cerebral abnormalities and subacute combined degeneration of the spinal cord.[16] The precise role of cobalamin in maintaining the integrity of the central nervous system has not been completely defined (see box on Clues for Distinguishing Cobalamin and Folate Deficiencies).

The demyelinating process involves patchy swelling of the myelin sheath followed by its breakdown (demyelination), leading to axonal degeneration. Microscopic foci coalesce with one another, giving the surface of the spinal cord (on cross section) a spongy appearance; later there is secondary Wallerian degeneration of long tracts. Patchy demyelination usually begins in the dorsal columns in the thoracic segments of the spinal cord (Fig. 40.8) and then spreads contiguously to involve corticospinal tracts. These lesions spread throughout the length of the cord and ultimately involve spinothalamic and spinocerebellar tracts. There is also degeneration of the dorsal root ganglia, celiac ganglia, the Meissner plexus, and the Auerbach plexus.

DIAGNOSTIC ISSUES: INFORMATION FROM THE PERIPHERAL SMEAR AND BONE MARROW ASPIRATE

Although not specific for megaloblastic anemia, macro-ovalocytes are the hallmark of megaloblastosis (see Fig. 40.7). However, only one-half with MCV values greater than 105 fL may have vitamin deficiency. In almost one-half of all cases, macrocytosis per se is not associated with megaloblastosis, and additional tests are necessary for complete diagnosis.

The frequency of hypersegmented PMNs (5% with five lobes or 1% with six-lobed PMNs) in patients with megaloblastic hematopoiesis is 98%. The sensitivity decreases to 78% in alcoholics, although the specificity of this finding is approximately 95%. With a combination of hypersegmented PMNs and macro-ovalocytosis, the specificity is 96%–98%, and the positive predictive value of folate or cobalamin deficiency is about 94%.[23] Hypersegmentation of PMNs is insufficiently sensitive, when compared with metabolite levels, to be used as a clinical tool in the diagnosis of mild cobalamin deficiency.[23]

Diagnostic Bone Marrow Aspiration

With the addition of highly sensitive serum tests for the specific diagnosis of cobalamin and folate deficiency, the need for a bone marrow test is often dictated by the urgency to diagnose megaloblastosis (with results available in an hour). For example, in the case of florid hematologic disease with or without neurologic disease suggestive of cobalamin or folate deficiency, bone marrow aspiration carried out as soon as possible is invaluable in assisting the rapid diagnosis of megaloblastosis. However, in the outpatient setting, when the patient has a characteristic peripheral smear, or for a patient with a primary neuropsychiatric presentation, a case can be made to initiate the sequence of diagnostic tests without bone marrow aspiration by proceeding with measurement of serum levels of vitamins or metabolites (see Table 40.2). Conversely, in a pregnant patient with pancytopenia with macro-ovalocytes, hypersegmented polymorphonuclear neutrophils, and reticulocytopenia with a history of noncompliance with prenatal supplements (and no neurologic findings suggestive of cobalamin deficiency), bone marrow aspiration may not be necessary to initiate therapy for a strong presumptive diagnosis of folate deficiency. If there is no evidence of response within 10 days, bone marrow aspiration is indicated.

CLUES FOR DISTINGUISHING COBALAMIN AND FOLATE DEFICIENCIES

Although the megaloblastic manifestations of cobalamin and folate deficiencies are clinically indistinguishable, certain distinct patterns in mode of presentation provide clues to the type and cause of deficiency. In general, the cause of folate deficiency can be found in the patient's recent past (within 6 months), primarily discerned from the history and physical examination. In contrast, the cause of cobalamin deficiency can remain obscure until specific tests to define the cause are carried out. In the past, by the time anemia was symptomatic, more than 80% of patients had neurologic manifestations, and in 50% this led to some incapacity. Perhaps as a result of widespread use of multivitamins containing folic acid among patients and even in the food given livestock in the West and widespread folate-fortification of food, the hematologic expression of cobalamin deficiency is often substantially attenuated, leading to pure neurologic presentations. Studies highlight the apparent inverse correlation between hematologic and neurologic presentations such that in a third of patients with cobalamin deficiency, the earliest signs are often purely neurologic, and symptoms related to paresthesias and diminished proprioception may cause the patient to see the physician. Based on the multiple potential causes (see box on Etiopathophysiologic Classification of Cobalamin Deficiency and box on Etiopathophysiologic Classification of Folate Deficiency), the warning that "what the mind does not know, the eyes do not see" is a caveat that cannot be taken lightly; failure to recognize cobalamin deficiency as the cause of neurologic disease and treatment of cobalamin deficiency with folate, or misdiagnosis of megaloblastosis as erythroleukemia represent significant extremes of deviation from the dictum *primum non nocere*. Areas of overlap in the symptoms of cobalamin or folate deficiency are related to megaloblastosis (i.e., common cardiopulmonary and some gastrointestinal manifestations). Although pure folate deficiency in the alcoholic with thiamine deficiency (i.e., Wernicke encephalopathy) and peripheral neuropathy is almost indistinguishable from and may mimic cobalamin deficiency, the remaining neurologic manifestations are uniquely characteristic of cobalamin deficiency. Folate deficiency in *adults* has not been unequivocally shown to give rise to neurologic findings. Coexistence of folate deficiency with neurologic disease should prompt investigations to rule out cobalamin and other nutrient deficiencies arising from dietary insufficiency or malabsorption.

MASKED MEGALOBLASTOSIS

The term *masked megaloblastosis* is reserved for conditions in which true cobalamin or folate deficiency with anemia is not accompanied by classic findings of megaloblastosis in the peripheral blood and bone marrow. This occurs when there is a coexisting condition that neutralizes the tendency to generate megaloblastic cells (usually involving reduction in RBC hemoglobinization, as in iron deficiency or thalassemia).[23] A wide RBC distribution width (RDW) on the Coulter counter readout in the presence of a "normal" mean corpuscular hemoglobin or MCV may reflect megaloblastic anemia[23] or dimorphic anemia (macro-ovalocytes plus microcytic hypochromic RBCs). Because megaloblastic white blood cells and precursors are unaffected by deficient hemoglobinization, these pathognomonic findings (giant myelocytes and metamyelocytes, and hypersegmented PMNs) remain; the latter may persist for up to 2 weeks after replacement with cobalamin or folate.[16] The recognition of masked megaloblastosis should initiate investigations to rule out iron deficiency, anemia of chronic disease, or hemoglobinopathies. Appropriate replacement with cobalamin or folate elicits a maximal therapeutic benefit only when iron deficiency is corrected. Conversely, if combined iron and cobalamin deficiency (total gastrectomy or pernicious anemia) or iron and folate deficiency (pregnancy) is treated with iron alone, megaloblastosis will be unmasked.

Although demyelination may also extend to the white matter of the brain, it is unclear whether the peripheral neuropathy is caused by a distinct lesion or results from spinal cord disease; the clinical manifestations may be extremely varied.[16]

Vegetarians with cobalamin neuropathy in India[104] had cognitive impairment in nearly one-half of 36 patients; it was mostly global with impaired recall and "serial sevens" (which are useful bedside tests of attention); impaired naming was found among one-quarter of the patients. Patients can present with anxiety, apathy, aggression, irritability, hallucinations, delusions, and disinhibition. Nearly one-half had abnormal evoked potential (using the oddball auditory paradigm), which revealed P300 latency that was reversible in 3 months of cobalamin replacement; in one-fifth P300 was unrecordable. Objective tests to document cobalamin neuropathy[104] include nerve conduction studies and motor- and sensory-evoked potentials,[105,106] visual pathway abnormalities,[107] and magnetic resonance imaging (MRI) that shows T2 hyperintensity and atrophy. Myelopathy is present in nearly all patients. In 70% of patients, there is neuropathy which is mainly axonal with some demyelinating features[108]; but there may also be reversible frontal-subcortical neurobehavioral and cognitive abnormalities ascribed to cortical and subcortical dysfunction.[109,110]

Among another cohort of patients with cobalamin neuropathy from the United States, 65% had mild, about 25% had moderate, and about 10% had severe neurologic deficits.[23] Paresthesias or ataxia were most commonly the first symptoms, and diminished vibratory sensation and proprioception in the lower extremities were the most common objective early signs. Although multiple neurologic syndromes were often seen in the same patient, the spectrum of objective signs could include loss of fine or coarse touch, decreased or increased deep tendon reflexes with spasticity or muscle weakness, urinary or fecal incontinence, orthostatic hypotension, amaurosis, dementia, psychosis, or mood disturbances.[23] Overall, although the neurologic deficits were mild in most cases, the severity was judged related to the duration of symptoms before diagnosis; not unexpectedly, those with the shorter duration of symptoms responded most to appropriate replacement.

ETIOPATHOPHYSIOLOGIC CLASSIFICATION OF COBALAMIN DEFICIENCY

I. Nutritional cobalamin deficiency (insufficient cobalamin intake)—vegetarians, poverty-imposed near-vegetarians, breastfed infants of mothers with cobalamin deficiency
II. Abnormal intragastric events (inadequate proteolysis of food cobalamin)—atrophic gastritis, hypochlorhydria, proton pump inhibitors, H_2 blockers
III. Loss/atrophy of gastric oxyntic mucosa (deficient intrinsic factor [IF])—total or partial gastrectomy (bariatric surgery), adult and juvenile pernicious anemia, caustic destruction (lye ingestion)
IV. Abnormal events in the small bowel lumen
    A. Inadequate pancreatic protease (R factor–cobalamin not degraded, so cobalamin not transferred to IF)
        1. Insufficient pancreatic protease—pancreatic insufficiency
        2. Inactivation of pancreatic protease—Zollinger-Ellison syndrome
    B. Usurping of luminal cobalamin (inadequate binding of cobalamin to IF)
        1. By bacteria-stasis syndromes (blind loops, pouches of diverticulosis, strictures, fistulas, anastomosis), impaired bowel motility (scleroderma), hypogammaglobulinemia
        2. By *Diphyllobothrium latum* (fish tapeworm)
V. Disorders of ileal mucosa/IF-cobalamin receptors (IF-cobalamin not bound to IF-cobalamin receptors [cubam])
    A. Diminished or absent IF-cobalamin receptors (cubam)—ileal bypass/resection/fistula
    B. Abnormal mucosal architecture/function—tropical/nontropical sprue, Crohn disease, tuberculous ileitis, amyloidosis
    C. IF-cobalamin receptor (cubam) defects—Imerslund-Gräsbeck syndrome
    D. Drug-effects—metformin, cholestyramine, colchicine, neomycin
VI. Disorders of plasma cobalamin transport (transcobalamin [TCII]-cobalamin not delivered to TCII receptors)—congenital TCII deficiency, defective binding of TCII-cobalamin to TCII receptors (rare)
VII. Metabolic disorders (cobalamin unable to be utilized by cells)
    A. Inborn enzyme errors—cblA to cblJ disorders (rare)
    B. Acquired disorders (cobalamin inactivated by irreversible oxidation)—nitrous oxide

ETIOPATHOPHYSIOLOGIC CLASSIFICATION OF FOLATE DEFICIENCY

I. Nutritional causes
    A. Decreased dietary intake—poverty and famine, institutionalized individuals (psychiatric/nursing homes)/chronic debilitating disease, prolonged feeding of infants with goat's milk, special slimming diets or food fads (folate-rich foods not consumed), cultural/ethnic diets (devoid of folate-rich foods) or prolonged cooking techniques (food folate destroyed)
    B. Decreased diet and increased requirements
        1. Physiologic—pregnancy and lactation, prematurity, hyperemesis gravidarum, infancy
        2. Pathologic
            (a) Intrinsic hematologic diseases involving hemolysis with compensatory erythropoiesis, abnormal hematopoiesis, or bone marrow infiltration with malignant disease
            (b) Dermatologic disease—psoriasis
II. Folate malabsorption
    A. With normal intestinal mucosa
        1. Drugs—sulfasalazine, pyrimethamine, proton pump inhibitors (via inhibition of proton-coupled folate transporter [PCFT])
        2. Hereditary folate malabsorption (mutations in PCFTs) (rare)
    B. With mucosal abnormalities—tropical and nontropical sprue, regional enteritis
III. Defective folate transport across the choroid plexus into the cerebrospinal fluid—cerebral folate deficiency (mutation or autoantibodies to folate receptors) (rare)
IV. Inadequate cellular utilization
    A. Folate antagonists (methotrexate)
    B. Hereditary enzyme deficiencies involving folate
V. Drugs (multiple effects on folate metabolism)—alcohol, sulfasalazine, triamterene, pyrimethamine, trimethoprim-sulfamethoxazole, diphenylhydantoin, barbiturates, carbazepine.[103]

OTHER EFFECTS OF COBALAMIN AND FOLATE DEFICIENCY

Cobalamin deficiency more often than folate deficiency can also result in sterility from the effects on the gonads. An unexplained finding is generalized melanin pigmentation that is reversible by specific nutrient replenishment. Cobalamin deficiency negatively affects bone development and maintenance,[111] leading to reduced bone mineral density.[112–115] Folate is also important for maintenance of regulatory T cells[116]; this may explain findings of combined immunodeficiency in hereditary folate malabsorption.[117]

SPECTRUM OF CLINICAL PRESENTATIONS WITH COBALAMIN DEFICIENCY

The age-specific presentations with cobalamin deficiency are discussed in Nutritional Cobalamin Deficiency. Classic presentations of nutritional cobalamin deficiency in resource-limited countries are often accompanied by iron deficiency, and especially among malnourished populations, many will also have folate deficiency.[118] Among vegetarians in resource-limited countries, cases with nutritional cobalamin deficiency may present in the second and third decades with pancytopenia, mild hepatosplenomegaly, fever, and occasionally thrombocytopenic bleeding.[23] Alternatively, a neurologic and psychiatric syndrome may develop with or independent of anemia.[23] In over a quarter of patients with cobalamin neuropathy in the United States, there was no reduction in the hematocrit despite neurologic disease, and only a minority of patients had combined hematologic and neurologic disease. Indeed, the higher the hematocrit, the more severe the neurologic disorder! Conversely, anemic patients may have no neurologic deficits. Importantly, the level of cobalamin may have no correlation with either the existence or the severity of neurologic disease.

BIOCHEMICAL INDICATORS OF EVOLVING DEFICIENCY

Early manifestations of negative cobalamin balance are increased serum methylmalonic acid (MMA) and total homocysteine levels (Table 40.2).[23] *This can occur when the total cobalamin in serum is still in the low-normal range.* Continued negative cobalamin balance leads to an absolute decrease in serum cobalamin level below normal. Normal levels of MMA and homocysteine rule out clinically significant cobalamin deficiency with virtually 100% certainty.[23]

Likewise, metabolic evidence for folate deficiency (i.e., increased serum total homocysteine level) can be found when serum folates are still in the low-normal range.

Laboratory tests are more likely to be accurate when there is a high pretest probability of a particular disease. This can, however, be more vexing in the case of diagnosis of early cobalamin deficiency when symptoms are subtle, nonspecific, or not yet fully manifest. If there is macrocytosis and cobalamin levels are borderline or just below normal, an unequivocal elevation of MMA will support the diagnosis. However, in elderly patients with anemia, there may be several other causes for anemia, and depending on the population studied, cobalamin deficiency may be only one among several possible causes in the differential diagnosis. This is when a modified therapeutic trial—in which a patient is treated with full doses of both cobalamin and folate for 10 days—and the lack of objective response would effectively rule out cobalamin (and/or folate) deficiency as a cause (see box on

TABLE 40.2 Stepwise Approach to the Diagnosis of Cobalamin and Folate Deficiency

Megaloblastic Anemia or Neurologic-Psychiatric Manifestations Consistent with Cobalamin Deficiency *Plus* Test Results on Serum Cobalamin and Serum Folate

Cobalamin[a] (pg/mL)	Folate[b] (ng/mL)	Provisional Diagnosis	Proceed With Metabolites?[c]
>300	>4	Cobalamin or folate deficiency is unlikely	No
<200	>4	Consistent with cobalamin deficiency	No
200–300	>4	Rule out cobalamin deficiency	Yes
>300	<2	Consistent with folate deficiency	No
<200	<2	Consistent with combined cobalamin *plus* folate deficiency	Yes
>300	2–4	Consistent with (1) folate deficiency or (2) an anemia unrelated to vitamin deficiency	Yes

Test Results on Metabolites: Serum Methylmalonic Acid and Total Homocysteine

Methylmalonic Acid (Normal, 70–270 nM)	Total Homocysteine (Normal, 5–14 μM)	Diagnosis
Increased	Increased	Cobalamin deficiency confirmed; folate deficiency still possible (i.e., combined cobalamin plus folate deficiency possible)
Normal	Increased	Folate deficiency is likely
Normal	Normal	Cobalamin and folate deficiency is excluded

[a] Serum cobalamin levels: abnormally low, less than 200 pg/mL; clinically relevant low-normal range, 200–300 pg/mL.
[b] Serum folate levels: abnormally low, less than 2 ng/mL; clinically relevant low-normal range, 2–4 ng/mL.
[c] Any frozen-over sample from serum folate/cobalamin determination can be subjected to metabolite tests.

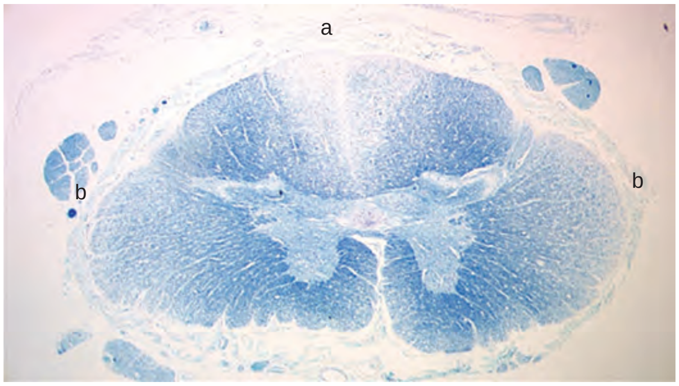

Figure 40.8 SPINAL CORD IN COBALAMIN DEFICIENCY. The cross section of the spinal cord stained with Luxol blue shows demyelination of the dorsal columns *(a)* and early demyelination of the lateral columns *(b)*.

Modified Therapeutic Trials). Alternatively, attribution of the cause of anemia to cobalamin (and/or folate) deficiency could be reasonably confirmed retrospectively if there was evidence for resolution of anemia following such therapy. Although reductions from high serum MMA and homocysteine values to baseline following therapy would also be confirmatory, this is impractical because of the expense of repeated testing.

BIOCHEMICAL EVALUATION OF COBALAMIN AND FOLATE DEFICIENCIES

Total Serum Homocysteine and Methylmalonic Acid Levels

Cellular nutrient *deficiency* of cobalamin or folate is reflected by decreased intracellular concentrations. Cobalamin deficiency perturbs methionine synthase activity; this results in substrate (homocysteine) buildup and elevated serum levels of homocysteine, which can be measured by a sensitive assay.[23] In addition, cobalamin deficiency perturbs the activity of methylmalonyl-CoA mutase, which leads to elevated serum MMA levels. Thus homocysteine and MMA are sensitive tests for cobalamin deficiency (see Table 40.2).

Folate deficiency also results in elevated levels of homocysteine because of reduced activity of the methionine synthase–catalyzed reaction.[23] Total homocysteine concentration, which comprises the sum of all homocysteine species in plasma/serum, including free and protein-bound forms, can be measured in plasma or serum.[23,120] In general, plasma levels are slightly lower. Thus an elevation of both homocysteine and MMA, while consistent with cobalamin deficiency, cannot rule out a combined cobalamin and folate deficiency (see Table 40.2).

Both homocysteine and MMA levels are elevated in patients with dehydration and renal failure. In addition, propionic acid derived from anaerobic fecal bacterial metabolism can also substantially contribute to methylmalonate production[6,121,122]; in this setting, the fraction of gut flora contribution to MMA can be reduced by treatment with metronidazole.

The normal value for serum homocysteine is 5.1 to 13.9 μM and serum MMA is 70 to 270 nM, and in general the higher the values, the more severe the clinical abnormalities.[23] However, there is a fairly wide range of “normalcy” in homocysteine values because of age-, creatinine-, gender-, diet-, and race-dependent variables.[120] Basal levels of MMA are usually less than 500 nM, and in renal failure, it rarely increases by more than 1000 nM.[23] If unseparated blood stands at room temperature, homocysteine levels will *increase* over 4 to 24 hours. Frozen serum (remaining from measurements of serum folate or cobalamin) can be used for serum MMA and homocysteine determinations.

Serum MMA levels are elevated in more than 95% of patients with clinically confirmed cobalamin deficiency (with median values of 3500 nM). Serum homocysteine concentrations are elevated in both cobalamin deficiency (median values of 70 μM) and folate deficiency (median values of 50 μM).

Serum Cobalamin Levels

For the most part, a low serum cobalamin level is an established biochemical indicator of cobalamin deficiency. In general, in patients with clinical cobalamin deficiency and megaloblastic anemia or neurologic disease consistent with cobalamin deficiency, the sensitivity of cobalamin concentration less than 200 pg/mL (or less than 148 pmol/L) exceeds 95%[123] when the pretest probability is high. However, up to 10% of adults with true cobalamin deficiency have cobalamin values in

MODIFIED THERAPEUTIC TRIALS

In a modified therapeutic trial, the intention is often to confirm the clinical suspicion that the patient does not have deficiency. This can be demonstrated by lack of response to full replacement doses of both vitamins (1 mg of folic acid orally for 10 days and 1 mg of cobalamin intramuscularly or subcutaneously daily for 10 days). Clinical scenarios in which such trials may be applicable (after drawing blood for serum cobalamin and folate levels) are as follows:

1. There is a clinical suspicion that the underlying disease is not caused by a vitamin deficiency, but this idea is not supported by results of clinical, morphologic, and biochemical evaluations. Such conditions include anemia with a megaloblastic bone marrow that may be due to underlying myelodysplastic syndromes, or acute leukemia, or the use of drugs that are known to induce megaloblastic anemia[119]; when time is of the essence in making the diagnosis; when the levels of cobalamin are likely to be falsely abnormal because of these diseases; or when there is underlying dehydration or renal dysfunction that predictably gives falsely high levels of metabolites, thereby precluding their diagnostic usefulness.
2. In other situations (i.e., pregnancy, acquired immunodeficiency syndrome, or alcoholism) with a multifactorial basis for anemia, the response or lack thereof to full replacement doses can eliminate cobalamin or folate deficiency and thereby narrow the (often extensive) differential diagnosis.
3. When severe anemia with megaloblastosis is clinically obvious and so serious that the physician cannot wait for the results of specific tests for deficiency, full doses of both vitamins are given, and if there is a response manifested by brisk reticulocytosis by days 5–7, retrospective assignment of the deficiency is based on the results of blood samples drawn before beginning the trial.

In all modified therapeutic trials, if there is no evidence of response within 10 days, bone marrow aspiration is indicated to identify another primary hematologic disease.

TABLE 40.3 Serum Cobalamin: False-Positive and False-Negative Test Results

Falsely Low Serum Cobalamin in the Absence of True Cobalamin Deficiency
Folate deficiency (one-third of patients)
Multiple myeloma
TCI deficiency
Megadose vitamin C therapy
Falsely Raised Cobalamin Levels in the Presence of a True Deficiency[a]
Cobalamin binders (TCI and II) increased (e.g., myeloproliferative states, hepatomas, and fibrolamellar hepatic tumors)
TCII-producing macrophages are activated (e.g., autoimmune diseases, monoblastic leukemias and lymphomas)
Release of cobalamin from hepatocytes (e.g., active liver disease)
High serum anti-IF antibody titer

[a] Although a low serum cobalamin level is not synonymous with cobalamin deficiency, 5% of patients with true cobalamin deficiency have low-normal cobalamin levels, a potentially serious problem because the patient's underlying cobalamin deficiency will progress if uncorrected.

IF, Intrinsic factor; *TC*, transcobalamin.

the low-normal (200 to 300 pg/mL) range and only metabolite testing with homocysteine and MMA will reveal the deficiency (see Table 40.2).

Thus a serum cobalamin concentration is less than 300 pg/mL in 99% of patients with clinical hematologic or neurologic manifestations of cobalamin deficiency,[23] and a cobalamin level of more than 300 pg/mL predicts folate deficiency or another hematologic or neurologic disease (see Table 40.2). However, a low serum cobalamin concentration is not synonymous with cobalamin deficiency, and several associated diseases and conditions can falsely raise or lower cobalamin levels (Table 40.3). Studies have also identified patients with true cobalamin deficiency who have cobalamin levels in the low-normal range. Among 173 unambiguously cobalamin-deficient patients[23] about 5% had normal cobalamin levels.

If the serum cobalamin test is broadly used as a screening test without clinical context, by virtue of the way normalcy is defined, 2.5% of nondeficient individuals will have low levels, which reflects our definition of the lower limit of normal for this test.[23] However, the finding in 2011 that the same blood sample can give different cobalamin results (one below normal versus one above normal) using different commercial assays has been of significant concern.[123] The more recent assays have periodically had such problems, apparently arising from a lack of transparency related to these tests, poor validation using low-cobalamin sera, and poor track record of continuous proficiency testing and tracking of assay performance.[123,124] It is a particularly serious issue when chemiluminescent tests for serum cobalamin give spuriously elevated levels and fail to detect clinically significant severe pernicious anemia. Such a false-negative test result has been attributed to the in vitro binding of anti-IF antibodies (present in the serum of patients with pernicious anemia) to the IF found in the manufacturer's reagent.[124,125] However, a reevaluation in 2014 of five different (currently used) automated cobalamin assays found that they are accurate and do not suffer from earlier problems.[126] Nevertheless, the principle that *"a clinical presentation which strongly suggests cobalamin deficiency should always lead to a therapeutic trial (with cobalamin replacement) even if the laboratory assay is nonconcordant"* must be upheld against future vagaries that can lead to dangerous false-negative errors in laboratory tests.

Therefore in the absence of availability of metabolite tests, if there are hematologic or neurologic findings that are consistent with clinical cobalamin deficiency, and the serum cobalamin level is normal or borderline low, it is entirely appropriate to empirically treat as for a cobalamin deficiency. If there is no improvement in hematologic parameters within a couple of months, provided there are no other conditions that limit a full response to cobalamin (e.g., iron deficiency or underlying thalassemia trait, hypothyroidism, renal disease, infection, alcoholism, or intrinsic hematologic disease in the bone marrow), cobalamin deficiency would be unlikely.

Cobalamin deficiency can falsely raise serum folate by 20% to 30% via methyl-folate trapping. This will seriously underestimate the prevalence of an associated folate deficiency among populations (particularly in resource-limited countries) where the dietary intake of both vitamins is consistently low.[118] Folate deficiency can also reduce serum cobalamin, but the mechanism is unclear. (See box on Summary of the Clinical Usefulness of Tests for Cobalamin and Folate Deficiencies.)

Serum Folate Levels

The serum folate level is clinically relevant and widely used. Indeed, when combined with a clinical picture of megaloblastic anemia and additional results of cobalamin levels, the serum folate concentration is the cheapest and most useful initial biochemical test to diagnose folate deficiency (see Table 40.2).[23] Microbiologic assays for

SUMMARY OF THE CLINICAL USEFULNESS OF TESTS FOR COBALAMIN AND FOLATE DEFICIENCIES

Within the clinical context of hematologic or neurologic features that suggest the diagnosis of cobalamin deficiency, if the cobalamin levels are suggestive but not definitive, then the methylmalonic acid (MMA) and homocysteine tests are an excellent gold standard test to confirm a clinical diagnosis. *Patients with clinical cobalamin deficiency usually have MMA values over 1000 nM and homocysteine values over 25 μM.* The MMA and homocysteine test results are much more sensitive than cobalamin levels and progressively increase much earlier than the drop in cobalamin levels; one or both metabolites was increased in 99.8% of more than 400 patients with proven cobalamin deficiency.[23]

folate, which measure all biologically active forms equally, have been replaced in the West by competitive folate-binding protein assays (from various commercial sources) that are indirect immunoassays, which rely on chemiluminescence methods. These tests are notorious for considerable lack of agreement with one another. Alignment with a new higher-order precision isotope-dilution liquid chromatography–tandem mass spectrometry assay, which demonstrates excellent agreement with the traditional *Lactobacillus casei* method,[127] will allow better standardization of the current competitive folate-binding protein assays.[128]

The serum folate level is highly sensitive to folate intake, and a single nutritious hospital meal may normalize it in a patient with true folate deficiency. Rapidly developing nutritional folate deficiency first leads to a decline in the serum folate level below normal (less than 2 ng/mL) in about 3 weeks because it is a sensitive indicator of negative folate balance.[16] However, in 25% to 50% of cases (predominantly alcoholics) with folate-deficient megaloblastosis, the serum folate levels may be below normal or borderline (2 to 4 ng/mL).[23] The serum folate level alone should never dictate therapy.

Based on the lower costs of serum cobalamin and folate compared with serum MMA and homocysteine levels, it is recommended (see Table 40.2) to first use the cheaper tests that can assist in the diagnosis of cobalamin and folate deficiency.[23] Clinicians should also restrict use of serum MMA and homocysteine *(a)* to patients with borderline cobalamin and folate levels; *(b)* to patients with existing clinical conditions known to be associated with difficulties in the interpretation of test results; *(c)* to situations in which cobalamin and folate levels are low, when a high MMA level is useful in confirming cobalamin deficiency (rather than attributing the condition to folate deficiency alone); and *(d)* to patients with clearly low serum levels but for whom there is an alternative explanation for the findings that caused an unusual serum cobalamin level to be obtained (e.g., a diabetic or alcoholic with peripheral neuropathy, an alcoholic with a high mean corpuscular volume and a low serum cobalamin without anemia). In these cases, serum levels of metabolites can assist in the diagnosis of vitamin deficiency. Diagnostic algorithms consistently stress the value of clinical data to improve the pretest probability of serum cobalamin and serum folate tests.[23] Without detailed clinical information, the combined test results for serum cobalamin, folate, and metabolite (homocysteine and MMA) are not sufficiently unambiguous to diagnose and distinguish cobalamin deficiency from combined cobalamin plus folate deficiency. In combined cobalamin plus folate deficiency, both vitamins would be needed to restore baseline values, particularly of homocysteine.[23]

When negative folate balance continues, hepatic folate stores are depleted in about 4 months.[16] This leads to tissue folate deficiency, which clinically correlates with a decrease in RBC folate (less than 150 ng/mL) by the microbiologic assay.[16] However, current RBC folate tests using different commercial kits have major limitations in sensitivity and specificity and are notoriously unreliable in alcoholics and in pregnancy; furthermore, a reduction of RBC folate also occurs in about 60% of patients with cobalamin deficiency.

The use of red-cell folates as a measure of long-term folate status is valid during clinical trials in which a single kit is used for a cohort of patients; however, it is *not* valuable for routine clinical diagnosis because of the significant variability of performance between different commercial kits and lack of clinical validation.[118,129] For these reasons, the serum folate level, although labile, is the preferred initial choice.[16,130–134]

However, there are important caveats to measuring serum folate levels in certain clinical settings (see box on Caveats Related to the Use of Laboratory Tests in Resource-Limited Countries).[118] First, the serum folate level can be artificially raised in a patient with either pure cobalamin deficiency or *combined* cobalamin and folate deficiency (Table 40.4). This is because cessation of the cobalamin-dependent methionine synthase reaction leads to a failure in utilization of intracellular folate for one-carbon metabolism. As a result, folate leaks out of cells into the plasma, thereby raising the patient's serum folate level; indeed, replacement of cobalamin alone will return the serum

CAVEATS RELATED TO THE USE OF LABORATORY TESTS IN RESOURCE-LIMITED COUNTRIES (SEE TABLE 40.4)[118]

Masking of Nutritional Folate Deficiency by Associated Cobalamin Deficiency and/or Malaria

In resource-limited countries, the majority of the population is either vegetarian or near-vegetarian; these diets are monotonous, low in fresh vegetables, fruits, and in animal-source foods. Such a diet predisposes to a combination of nutritional cobalamin and folate (and iron) deficiencies, particularly among women and children. With cobalamin deficiency, the failure in utilization of intracellular folate for one-carbon metabolism results in folate leaking out of cells, thereby raising the serum folate.[16] What this means is that the presence of cobalamin deficiency will consistently *mask* the coexistence of folate deficiency whenever there is an (undue) over-reliance by the clinician in using the biomarker of the serum folate level as a gold standard to diagnose folate deficiency. This is a surprisingly common error in the contemporary literature[118]—a fact that inadvertently downplays (with disastrous consequences) the seriousness of folate deficiency among millions of these particularly vulnerable women and children. Added to this is the fact that in many such regions, there is also the scourge of endemic malaria with its propensity for hemolysis (and release of the 30-fold higher red cell folate into plasma). Here too, the serum folate level will yield normal-to-high values and predictably underestimate the tissue folate status, thereby masking the diagnosis of mild-to-moderate folate deficiency in these very patients who desperately require folate to support compensatory hematopoiesis and for growth and development (see Table 40.4 and Summary of the Clinical Usefulness of Tests for Cobalamin and Folate Deficiencies).

The only solution to correctly identifying whether these patients are at risk for nutritional folate deficiency is to obtain a good dietary history and identify those at risk for nutritional insufficiency.[135] (Other formal assessment includes use of 24-h food recall, estimated/weighed record, or locally validated food-frequency questionnaires to evaluate the quality and quantity of nutrients consumed.)[135] *Indeed, knowledge of dietary folate and cobalamin intake should always take precedence over the results of conventional blood tests for folate deficiency, which are flawed in this clinical setting.* From the practical standpoint, all individuals at risk for nutritional anemia caused by deficiency of iron, folate, and cobalamin (including both adults[135] and children[136]) should be given prophylactic oral cobalamin, folate (and iron) replacement; and in malarious zones, these should be combined with antimalarial drugs and insecticide-treated bed nets.

Overreliance on Laboratory Data at the Expense of Clinical Information—A Case Study[118]

The majority of women and children in resource-limited countries suffer from combined nutritional iron, cobalamin, and folate deficiency—the three key causes of nutritional anemia. There are often additional congenital or acquired causes for hemolytic anemia in a single individual, such as malaria, bacteremia, hemoglobinopathy, or glucose-6-phosphate dehydrogenase deficiency. There is therefore potential for a clinician to make several critical interrelated errors: *First*, despite dire poverty and near-famine conditions, mere inattention and failure to obtain a good dietary assessment of (deficient) iron, cobalamin, and folate intake in these vulnerable patients will lead to an underestimation of the extent of deficiency of these nutrients.[118] *Second*, this can be coupled with a lack of appreciation of the potential for one deficient micronutrient to have on the blood test result of another. For example, cobalamin deficiency or hemolysis will invariably raise the serum folate level (from a below-normal level into the normal range) and thereby lead to an underestimation (and misdiagnosis) of the fact of *tissue* folate deficiency.[118] *Third*, a failure to replace all three deficient nutrients in a given individual will invariably lead to a failure in restoring hemoglobin values to optimum; indeed, replacing one or even two out of three key missing nutrients cannot possibly be expected to secure a complete resolution of anemia.

Continued

TABLE 40.4 **Serum Folates Are Misleadingly Elevated in Cobalamin (Vitamin B_{12}) Deficiency and/or Malaria Which Are Both Common in Resource-Limited Settings**[a,b]

	Serum Folates	Erythrocyte Folates	Serum Cobalamin
Pure folate deficiency	Low	Low	Normal/low[b]
Pure cobalamin deficiency	Normal/high[b,c]	Low[b,c]	Low
Folate *plus* cobalamin deficiency	Normal[b]	Low	Low
Pure malaria	Normal[b]/high[b,d]	High[b,e,f]	Normal
Malaria *plus* folate deficiency	Normal[b]	Normal[b]/high[b]/low	Normal
Malaria *plus* cobalamin deficiency	Normal[b]/high[b,d]	Normal[b]/high[b,f]	Low
Malaria *plus* folate *plus* cobalamin deficiency	Normal[b]/high[b,d]	Low/normal[b,f,g]	Low

[a] Both cobalamin deficiency and clinical malaria and other hemolytic states can complicate the diagnosis of folate deficiency using tests for serum- or erythrocyte-folate concentration.[118]

[b] Indicates misleading values in the clinical settings shown on the left. The information presented in this table has been synthesized from several sources (see text and references).[118]

[c] Cobalamin deficiency is accompanied by inability to use folates for one-carbon metabolism, so folates leak out of erythroid precursors into serum.

[d] Release of the 30-fold excess folate from infected erythroid precursors, reticulocytes, and mature erythrocytes during hemolysis raises serum folate levels. (An as-yet-unknown quantity of folate is released into serum when folate-rich hepatocytes are destroyed during the exoerythrocytic hepatic phase of malaria.)

[e] Hemolysis induces a compensatory reticulocytosis; these reticulocytes are richer in folate than mature erythrocytes.[16,118]

[f] *Plasmodium falciparum* can also synthesize folates in erythrocyte cultures in vitro and raises erythrocyte folates in animal models with high levels of parasitemia.

[g] Reticulocytopenia in severe *Plasmodium falciparum* malaria, caused by either combined cobalamin deficiency *plus* folate deficiency, which can trigger a reticulocytopenic (megaloblastic) crisis, or cytokine-induced inhibition of hematopoiesis, will negate an expected rise in erythrocyte folates.

From Antony AC. Megaloblastic anemias. In: Goldman L, Schafer A, eds. *Cecil Medicine*. Vol 1, 25th ed. Philadelphia, PA: Elsevier-Saunders; 2015:ch. 164, pp. 1104–1114.

folate level to baseline.[16,118] Thus associated nutritional cobalamin deficiency has the potential to consistently mask the coexistence of mild-to-moderate folate deficiency if the unwary clinician uses the serum folate level as a gold standard for diagnosing folate deficiency in this clinical setting. Second, such patients (with combined nutritional folate *and* cobalamin deficiency) often reside in malarious regions where there may be ongoing hemolysis from malaria per se as well as hemolysis from associated hemoglobinopathies that are common in these regions (e.g., thalassemia, sickle cell disease, glucose-6-phosphate dehydrogenase deficiency). In a patient with malaria during hemolysis of *Plasmodium falciparum* infected erythroid precursors, reticulocytes, and mature erythrocytes, there will be substantial release of the 30-fold more folate-rich intraerythrocyte contents *into* serum, thereby artificially raising the baseline serum folate level. Moreover, red cells normally contain substantial amounts of *various forms of folate*, that is, 5-methyltetrahydrofolate (monoglutamates) and folate-polyglutamates of different glutamate chain lengths[16,118]; whereas clearance of such released folate monoglutamates would be hindered with associated cobalamin deficiency,[118] we also know that the released folate polyglutamates are also inefficiently transported back into cells relative to monoglutamates,[118] thereby also resulting in poor clearance. In this clinical context, the current assays for serum folate may not consistently discriminate among these forms of folates. The net result is that a *high* serum folate could be reported in all such individuals with malaria, *even when the patient's tissue folates are significantly depleted*.[118] This predictable masking of tissue folate depletion *argues against* the use of serum tests for folate deficiency in this clinical setting,[118] where a dietary history of the intake of folate-rich foods in the diet is a better clinical method to assess folate status. (See box on Caveats Related to the Use of Laboratory Tests in Resource-Limited Countries and Table 40.4.)

Other Tests

The clinical use of low holo-TCII (holo-TCII) levels, to provide information on the extent of saturation of serum TCII as an early marker of cobalamin homeostasis[137] or to diagnose cobalamin deficiency in lieu of serum cobalamin values, is still unclear. This test has not yet been sufficiently clinically validated[123] to define sensitivity, specificity, and other clinical confounders that can alter the results; it has neither supplanted the use of the serum cobalamin test for diagnosis of deficiency, nor is it widely available or used in United States.[4,6,138,139]

PATHOGENESIS OF COBALAMIN DEFICIENCY

Nutritional Cobalamin Deficiency

Vegetarian diets can be classified as lactovegetarian, ovovegetarian, lacto-ovovegetarian, or vegan, respectively, if they include dairy products, eggs, dairy products and eggs, or no animal products at all.[7,8] However, all these vegetarian diets contain insufficient amounts of cobalamin. Therefore, *all* vegetarians are in various stages of progressive cobalamin depletion and moving inexorably toward cobalamin deficiency.[7–9] This warrants early supplementation with cobalamin.

In addition, the vast majority of those living in resource-limited countries subsist on a relatively monotonous diet that is intrinsically low in animal-source foods (that are more expensive than plant-based diets). Although not strictly considered vegetarians, such individuals are better classified as "near-vegetarians"[7,8] and should also be supplemented with cobalamin. Cobalamin deficiency has been widely reported among 45% of Northern Chinese women,[140] and in up to 85% of Indian adolescents[141] and 65% of newborns.[142] In Pakistan,[143] among those with megaloblastic anemia (hemoglobin $< 8\,g/dL$), nearly 80% had cobalamin deficiency. Surprisingly, even those consuming "Mediterranean diets" that are rich in fruits and vegetables but low in animal-source protein are at risk for cobalamin deficiency; among 180 pregnant women, cobalamin deficiency was found in 72% of mothers and 41% of babies.[144]

The fetus is dependent on the mother's cobalamin stores for a sufficient quota of cobalamin at birth; a close correlation exists between low maternal serum and breast milk cobalamin concentrations and cobalamin insufficiency in the infant.[4,145] Therefore when mothers do not consume sufficient amounts of animal-source foods, they themselves are at risk for nutritional cobalamin deficiency, and their infants will have smaller stores of the vitamin at birth.[16,146] Although the dictum is that infants should be exclusively breastfed for the first 6 months of life, a large percentage of mothers in resource-limited countries had evidence of cobalamin deficiency.[7,147,148] For example, three-quarters of a cross section of

366 pregnant urban women in South India had cobalamin deficiency.[135] So there is an imperative to raise these values in women and in babies. An important series of studies has shown that treatment of the mother during pregnancy[149] or even the infant shortly after delivery will promptly reverse preexisting cobalamin deficiency.[150]

Cobalamin-deficient infants can present with a spectrum of clinical findings, ranging from feeding difficulties and refusal of both breast milk and complementary food by regurgitation (which results in further failure to thrive) to motor and social retardation, reflecting a developmental delay. The child is persistently drowsy and rarely sits up or makes eye contact.[7] There may be lemon-tint jaundice with hypotonia, insufficient head control, and delayed spontaneous turning. There can be brownish-black areas of hyperpigmentation in the dorsal fingers and toes as well as over the medial thighs, arms, and axillae (which usually resolve within 3 months of therapy). Evidence of megaloblastic anemia may be masked with superimposed iron deficiency. If left untreated, there is growth retardation with reduced height and weight, and reduced head circumference with cranial MRI showing delayed myelination and frontoparietal cortical atrophy in affected infants[151]; these can also be reversed within 3 months of cobalamin replacement. Treatment results in a dramatic increase in alertness and responsiveness of the child, who is now miraculously transformed into a normal child who, within a few days, rolls over spontaneously, makes eye contact with its mother, and is much more interested in the surroundings. Any previous abnormal movements (tremors, chorea, or myoclonus) may regress but transiently return within a few days to affect the face or tongue; however, these will resolve in 2 to 3 months.[152] Cobalamin deficiency often resurfaces during wartime, which invariably leaves women and their infants malnourished.[153]

Infants in the West fed a macrobiotic diet (vegan-like with occasional servings of fish) must be rapidly replenished with full doses of cobalamin before switching to a cobalamin-rich diet. Otherwise, up to 20% continue to have low cobalamin status, which can lead to impaired psychomotor functioning well into youth and later adolescence with compromise in faculties related to reasoning, abstract thinking, and learning ability.[154]

When children in resource-limited settings grow up on the same monotonous diet as their parents, they are at risk for combined cobalamin, folate (and iron) deficiency.[7,155–158] *This problem of vertical intergenerational transfer of a deficient "bank balance" of minerals and micronutrients from one generation to another has been documented in all resource-limited countries*. These affected children with preexisting depleted stores of cobalamin, folate (and iron), and imminent deficiency, who are the unwitting victims of circumstance, limp on through life with cognitive dysfunction and lower intelligence quotient and emotional intelligence (when compared with their better nourished counterparts in resource-rich countries). When they move on into adolescence and (often premature) young motherhood, they pass on their deficient "bank balances" vertically to the next generation and so the cycle continues *ad infinitum*. The number of such affected individuals worldwide is probably in the hundreds of millions.

Longitudinal studies from the West among women who apparently consume a balanced nonvegetarian diet confirm that pregnancy places an additional stress on the mother's cobalamin stores and can lead to metabolic evidence of cobalamin deficiency.[159–161] This can negatively affect their breastfed infants' cobalamin status at 6 weeks; indeed, over two-thirds of Norwegian infants of otherwise healthy mothers had a metabolic profile consistent with cobalamin deficiency, which reverted to normal after cobalamin replenishment.[160,161] Among infants with only minor developmental delays and feeding difficulties (regurgitation) and biochemical evidence of cobalamin deficiency, those treated with cobalamin responded with significant clinical benefit, a fact that underscores the importance of cobalamin in postnatal neurodevelopment.[162] Thus it is likely that many more breastfed infants in the West probably need cobalamin supplements early in life, as do their mothers in preparation for pregnancy.[12]

Intragastric Events Leading to Cobalamin Malabsorption

Inadequate Dissociation of Cobalamin From Food Protein

Dietary cobalamin is bioavailable only after proteolytic digestion of food by gastric acid and pepsin. Failure to release cobalamin from food protein can lead to food-cobalamin malabsorption and frank cobalamin deficiency despite the presence of IF.[23]

Congenital Intrinsic Factor Deficiency[163]

Congenital IF deficiency arising from mutations in gastric IF,[163,164] resulting in complete loss of IF, can be transmitted as an autosomal recessive trait and expressed in homozygotes by the age of 2 years as severe megaloblastic anemia (less than 100 cases reported).[163] Dysfunctional IF may lead to only a mild abnormality in binding to cobalamin and result in a delayed presentation into the second decade.[23]

Loss or Atrophy of Gastric Oxyntic Mucosa

IF deficiency, which arises from atrophy of gastric parietal (oxyntic) mucosal cells, can be caused by total or partial gastrectomy (bariatric surgery); by autoimmune destruction, as observed in adult Addisonian pernicious anemia or, rarely, in a similar disease in children (juvenile pernicious anemia); and after destruction of gastric mucosa by caustic (lye) ingestion.

Total gastrectomy invariably leads to cobalamin deficiency in about 5 years (range, 2 to 10 years); indeed, longitudinal follow-up revealed that all 176 patients developed cobalamin deficiency within 4 years, with earlier clinical presentations occurring in those with lower cobalamin status preoperatively.[165] This condition is often associated with iron deficiency,[16] warranting routine prophylactic cobalamin and parenteral iron replacement.

By contrast, after partial gastrectomy, the degree of cobalamin deficiency depends on the size of the remaining gastric remnant. Cobalamin deficiency eventually develops in 10% to 20% of patients at 8 years with a minority (about 5%) developing overt clinical manifestations from a combination of decreased IF secretion, hypochlorhydria, intestinal bacterial overgrowth of cobalamin-consuming organisms, and iron deficiency. It is more common in Billroth II than in Billroth I surgery, and in subtotal than in partial gastrectomy. Morbidly obese patients treated surgically with gastric bypass also have more food-cobalamin malabsorption than patients treated with vertical banded gastroplasty.[23] Even after laparoscopic Roux-en-Y gastric bypass, and despite oral multivitamin supplementation, iron deficiency was seen in one-half of patients and cobalamin deficiency seen in one-quarter at 3 years[166]; therefore all such patients need prophylactic cobalamin and parenteral iron.

Absent Intrinsic Factor Secretion and Pernicious Anemia

A common cause of cobalamin malabsorption is pernicious anemia, an autoimmune disease in which the fundamental defect is atrophy of the gastric (parietal cell) oxyntic mucosa that eventually leads to the complete absence of IF and hydrochloric acid secretion (Fig. 40.9). The autoimmune gastritis (leading to chronic atrophic gastritis) associated with pernicious anemia involves the fundus and body of the stomach, and the histologic appearance of the gastric mucosa (infiltration with plasma cells and lymphocytes) is strongly reminiscent of autoimmune lesions.[6,167,168] Because cobalamin is absorbed only by binding to IF and uptake by ileal IF-cobalamin receptors, the net consequence is severe cobalamin malabsorption leading to cobalamin deficiency.

The annual incidence of pernicious anemia is approximately 25 new cases per 100,000 persons older than 40 years. Although the average age of onset is about 60 years, pernicious anemia is no respecter of age, race, or ethnic origin. The predisposition to developing pernicious anemia may have a genetic basis, but neither the

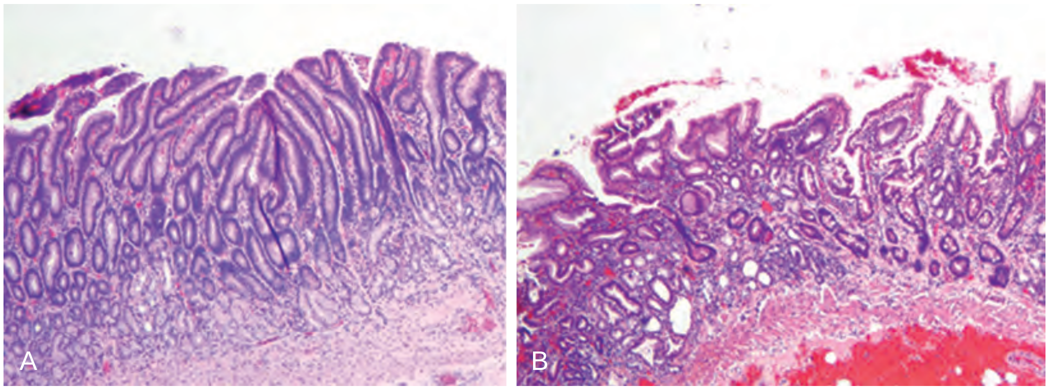

Figure 40.9 HISTOLOGIC FEATURES OF STOMACH IN PERNICIOUS ANEMIA COMPARED TO NORMAL. The normal gastric mucosa (A) is contrasted to that seen in pernicious anemia (B), in which there is atrophy of gastric glands, intestinal metaplasia with goblet cells, and loss of parietal cells (not visible at this magnification).

mode of inheritance nor the initiating events or primary mechanism is precisely understood. There is a positive family history for about 30% of patients, among whom the risk for familial pernicious anemia is 20 times as high as in the general population; about 20% of siblings of patients are projected to develop pernicious anemia by the age of 90 years, and pernicious anemia has developed concordantly in identical twins. There is a significant association of pernicious anemia with other autoimmune diseases,[16] including Graves disease (30%), Hashimoto thyroiditis (11%), vitiligo (8%), Addison disease, idiopathic hypoparathyroidism, primary ovarian failure, myasthenia gravis, type 1 diabetes mellitus, and adult hypogammaglobulinemia.[16,23]

Autoimmune gastritis progresses over decades to atrophic body gastritis and pernicious anemia. Serum anti-IF antibodies are highly specific (100%) for pernicious anemia, but the sensitivity is only about 50%. Earlier, the clinical use of anti-parietal cell antibodies was limited because of low specificity. This necessitated use of additional surrogate markers (high serum gastrin and low pepsinogen I levels) that reflected loss of acid- and IF-secreting parietal (oxyntic) cells. However, newer enzyme-linked immunosorbent assays (ELISA) for anti-parietal cell antibodies, which are directed against gastric H^+/K^+ ATPase, are 30% more sensitive than previous (immunofluorescence) assays. A reanalysis of the clinical utility of combining anti-IF and newer anti-parietal cell antibody tests to noninvasively diagnose pernicious anemia points to this approach as very promising.[169] Thus among 81 patients with biopsy-proven atrophic body gastritis and pernicious anemia, combining anti-IF antibodies (37% sensitivity; 100% specificity) with newer anti-parietal cell antibodies (sensitivity 91%; specificity 90%) significantly increased their diagnostic performance for pernicious anemia, yielding overall 73% sensitivity while maintaining 100% specificity.[169]

Juvenile pernicious anemia can manifest in the second decade with severe cobalamin deficiency in conjunction with many of the associated endocrinopathies and autoantibodies observed in adults.[16]

Undiagnosed pernicious anemia is common among free-living elderly persons (over 60 years of age) who have only minimal clinical manifestations of cobalamin deficiency (i.e., 1.9% of a Southern California survey population had unrecognized and untreated pernicious anemia).[170] The prevalence was 2.7% in women and 1.4% in men, but 4.3% of the African American women and 4.0% of the women of European descent had pernicious anemia.

Abnormal Events in the Small Bowel Lumen

Insufficient Pancreatic Protease

About 30% of patients with severe pancreatic insufficiency fail to degrade R proteins, which will lead to impaired transfer of cobalamin from R protein to IF. Pancreatic extract will normalize cobalamin malabsorption.[16]

Inactivation of Pancreatic Protease

Pancreatic protease can be inactivated by massive gastric hypersecretion arising from a gastrinoma in Zollinger-Ellison syndrome.[16] The continued low pH of the luminal contents reaching the ileum may also perturb interaction of the IF-cobalamin complex with IF-cobalamin receptors (which requires a pH above 5.4).

Usurpation of Luminal Cobalamin

The near-sterile condition of the small bowel is maintained by a combination of the mechanical cleansing action of peristalsis and the chemical action of gastric acid. Disorders conducive to relative stasis, impaired motility, and hypogammaglobulinemia are predisposing factors that favor colonization by bacteria. Many of these bacteria can take up free cobalamin, but not IF-bound cobalamin. However, if colonization extends proximally to the locus at which IF and cobalamin interact, significant cobalamin may be usurped before it can bind to IF.[16] This cobalamin malabsorption can be corrected to some extent by a 7- to 10-day course of antibiotic therapy.

Approximately 3% of individuals infested with the fish tapeworm *Diphyllobothrium latum*, which avidly usurps cobalamin for growth,[16] can develop frank cobalamin deficiency. Humans become infected when they eat partially cooked or raw fish containing plerocercoids, which develop into adult worms in the jejunum in about 6 weeks, growing to a length of 10 m, with up to 4000 proglottids[16]; when these worms lay eggs, the life cycle is repeated. After ova have been identified in the stools, expulsion of the worms by oral praziquantel (10 to 20 mg/kg as a single dose) and cobalamin replenishment is curative.

Disorders of Ileal Intrinsic Factor–Cobalamin Receptors or Mucosa

Absence of Intrinsic Factor–Cobalamin Receptors

The distal ileum has the greatest density of IF-cobalamin receptors. Disease or removal of only 1 to 2 feet of terminal ileum by resection or bypass reduces ileal IF-cobalamin receptor numbers for interaction with IF-cobalamin, resulting in cobalamin malabsorption.[16,23]

Defective Intrinsic Factor–Cobalamin Receptors or Post-Intrinsic Factor–Cobalamin Receptor Defects

Imerslund-Gräsbeck syndrome is a term used collectively for a heterogeneous group of congenital (autosomal recessive) disorders in children arising from biallelic mutations (in 80% of cases) involving either the *CUBN* or *AMN* genes that constitute the functional IF-cobalamin receptor (i.e., cubam).[171] This results in selective cobalamin malabsorption. Children present between 3 and 10 years of age with megaloblastic anemia and neurologic presentations with low serum cobalamin levels associated with mild, persistent, benign proteinuria (in 90% of cases). Because renal cubam also participates in renal tubular absorption of albumin, this explains the proteinuria in Imerslund-Gräsbeck syndrome. Diagnosis requires analysis of mutational status of gastric IF, *CUBN*, and *AMN* genes.[164,171]

Drug-Induced Defects

Long-term use of H_2 antagonists and/or proton pump inhibitors may interfere with the eventual handover of food-cobalamin to IF, especially in those with preexisting borderline cobalamin stores. Long-term treatment with metformin can interfere with IF-cobalamin binding to ileal IF-cobalamin receptors (cubam)[172] and increases risk for cobalamin deficiency over time,[173] warranting replacement therapy. Cholestyramine, colchicine, and neomycin probably also impair transepithelial transport of cobalamin.[16]

Disorders of Plasma Cobalamin Transport

Polymorphism or absence of TCI can be associated with low cobalamin levels, but the MMA and homocysteine levels are normal. By contrast, either deficiency or defective TCII can present with megaloblastic anemia in infancy; these conditions can nevertheless be associated with normal cobalamin levels (because TCI, which binds over 75% of serum cobalamin, is normal). However, there will be metabolic evidence of cobalamin deficiency that can be reversed by daily or biweekly injections of 1 mg of cobalamin, which ensures passive cobalamin delivery into cells. Rare mutations in the gene for the TCII receptor (*CD320*) have also been identified.[174]

Disorders of Intracellular Cobalamin Use

Congenital Metabolic Defects of Cobalamin Metabolism: Cobalamin Mutants A to J

Given the multitude of chaperones or transporters involved in escorting cobalamin intracellularly to their destination to function as coenzymes for methionine synthase and methylmalonyl-CoA mutase,[175] it is not difficult to envision that there would invariably be rare inborn errors of cobalamin metabolism where one of these escorts or transporters is missing. The combination of megaloblastic anemia with increased levels of homocysteine or MMA, or both, in serum and urine despite normal cobalamin and folate levels should suggest an inborn error of cobalamin metabolism.[176] The inherited defects of cobalamin use (see Fig. 40.3) are heterogeneous and are empirically defined as cobalamin mutations A to J (cblA to cblJ).[176] These infants must be differentiated from those with nutritional cobalamin deficiency who could have similar clinical features. Patients suspected of having an inborn error of metabolism should be evaluated by experts who have published extensively on this topic.[175]

Functional Cobalamin Deficiency After Nitrous Oxide Exposure

Nitrous oxide (N_2O) inactivates coenzyme forms of cobalamin by oxidizing the fully reduced cob(I)alamin to cob(III)alamin; this results in a state of functional intracellular cobalamin deficiency. This syndrome was first identified in patients with tetanus given nitrous oxide for up to 6 days.[16] Subsequently, persons exposed to nitrous oxide for open heart surgery and through chronic (recreational, accidental, or occupational) exposure have been recognized as being at high risk for developing megaloblastosis and cobalamin-deficient neuromyelopathy.[16,177] Megaloblastosis develops within 24 hours and lasts less than 1 week after a single exposure. Severe neurologic deficits have been reported after prolonged intraoperative exposure to nitrous oxide in patients with unsuspected or even borderline cobalamin deficiency.[23] The neurologic syndrome is usually seen with chronic intermittent exposure. (See box on Subclinical Cobalamin Deficiency.)

SUBCLINICAL COBALAMIN DEFICIENCY

The entity of subclinical cobalamin deficiency is present when there is biochemical evidence for cobalamin deficiency, reflected by a low cobalamin value (and increased methylmalonic acid and homocysteine) but without overt clinical manifestations. Although dependent on the population studied, the frequency of (silent) subclinical cobalamin deficiency in the United States is suspected to be 10 times higher than classic (overt) cobalamin deficiency that is found in 1%–2% of the population. Many elderly persons may have various symptoms consistent with aging (including fatigue, cognitive changes, lower quality-of-life measures, and subtle symptoms of neuropathy) that cannot be directly attributed to cobalamin deficiency, despite the fact that these very symptoms are often seen in symptomatic cobalamin deficiency.[178] Often this triggers testing with a serum cobalamin test, and a borderline result that can either spontaneously revert to normal, or minimally fluctuates above or below the cutoff value, or remains stable without change over many years; this in turn generates a new set of problems, including the need to label this entity and thereby make clinical decisions.

Although some experts do not feel obliged to treat, preferring to wait for overt symptoms, others feel ethically bound to treat even without overt clinical manifestations; the latter position is based on the fact that such clinical manifestations can be very subtle and are detected only by sophisticated neurophysiologic or imaging studies (which are both expensive and impractical in routine clinical practice). In support of earlier therapy in this clinical setting, there is compelling clinical evidence that combined B-vitamin supplementation to reduce homocysteine can reduce brain atrophy[178] and both cognitive and clinical decline (see section on Hyperhomocysteinemia for additional discussion).[179]

Therefore, after first replenishing potentially depleted cobalamin stores with parenteral cobalamin therapy, oral supplementation for up to 6 months on and 6 months off can normalize cobalamin status in most patients[180] as an alternative to continuous therapy. A key factor in such decisions is the benefit in avoiding progressive brain dysfunction and relatively low cost of cobalamin (and lack of side effects).

PATHOGENESIS OF FOLATE DEFICIENCY

Folate deficiency is usually recognized in the course of certain clinical presentations that predispose to negative folate balance and subsequent deficiency. It is instructive therefore to conceptualize cellular folate deficiency as arising from etiologic categories of decreased supply (i.e., reduced intake, absorption, transport, or use) or increased requirement (i.e., metabolic consumption, destruction, or excretion). However, in the same patient more than one mechanism may result in net folate deficiency. The precise contribution of one mechanism over the other is often not obvious, and specific tests to define each mechanism are not routinely available for clinical use. Thus the clinical context is especially important. Megaloblastic manifestations of folate deficiency are discussed within the context of the history and physical examination (discussed later). Cases of neuropathy in adults attributed to folate deficiency are rarely encountered; when they are, the possibility of alcoholism with thiamine deficiency must be considered. And every patient with neuropathy, myelopathy, or psychiatric manifestations associated with megaloblastosis must be investigated in detail to rule out cobalamin deficiency. Gastrointestinal megaloblastosis begets further folate malabsorption, which propagates a vicious cycle of folate deficiency in the short term and cobalamin deficiency in the long term. With the exception of drug-induced defects or inborn errors of folate metabolism that result in decreased use of intracellular folates, all causes, irrespective of mechanism, result in reduced net delivery of folates to normal proliferating cells.

Nutritional Causes of Folate Deficiency

The body stores of folate are adequate for only about 4 months[16] although those with higher folate stores could take longer to become frankly deficient.[181] Individuals who are chronically in negative folate balance may only require a brief "nudge"—from superimposition of an associated illness that leads to hemolysis, anorexia, or folate malabsorption—to "tip" them into frank folate deficiency. This is particularly common in resource-limited countries, where decreased seasonal availability of folate-rich foods, poverty, consumption of a poorly balanced, monotonous, cultural/ethnic diet (of wheat, maize, rice, and well-cooked lentils/beans and vegetables), is further compromised by prolonged cooking which destroys folate. Collectively, these factors contribute to the development of folate deficiency.[16,23]

Folate deficiency varies among countries and even within different regions of a country and is influenced by the economic status and net folate content of the ethnic diet consumed by the population under study. Before folate fortification of food, about 20% of the US population had low-folate status. In African countries, the prevalence of folate deficiency ranged from a low of 20% in Benin, to 30% in Zimbabwe, to nearly 60% in Sudan[182]; these differences are likely due to the variable masking of folate deficiency by associated cobalamin deficiency and/or hemolysis (see box on Caveats Related to the Use of Laboratory Tests in Resource-Limited Countries[118]). In Sri Lanka, one-half of schoolchildren had low-folate status, and in India 60% to 80% of women of childbearing age have nutritional folate deficiency.[16,118]

In Western countries, food faddism, alcoholism, or unbalanced slimming diets usually lead to decreased folate intake in young to middle-aged individuals.[16] Edentulous or infirm persons or neglected older adults who are too ill to prepare their meals, and patients with psychiatric problems, are at risk for nutritional folate deficiency (see box on Etiopathophysiologic Classification of Folate Deficiency).[16]

Folate fortification of foods in the West has led to widespread elimination of folate deficiency and related anemia,[183,184] leading to questions of whether testing for folate deficiency is even justified.[185,186] However, vigilance must be exercised particularly among women on low carbohydrate diets (not using folate supplements) and the elderly who are still at risk for both folate and cobalamin deficiency.[187,188]

Pregnancy and Infancy

Pregnancy and lactation are associated with significantly higher folate requirements (over 400 μg/day) for growth of the fetus, placenta, breast, and other maternal tissues.[189] Folate requirement increases throughout pregnancy and is maximal near term. There is also a three-fold increased urinary loss of folate during pregnancy because of a lower renal threshold. Poor preparation for pregnancy, with a poorly balanced diet and preexisting multifactorial nutritional anemia that remains unaddressed, is a major factor accounting for serious pregnancy complications and adverse birth outcomes. Therefore, additional folate during pregnancy is required to prevent both pregnancy complications (preeclampsia, placental abruption or infarctions, recurrent miscarriage) and poor pregnancy outcomes (preterm delivery, NTDs, congenital heart defects, and intrauterine growth retardation). Low-folate status associated with short interpregnancy intervals or twin pregnancies also predisposes to preterm births.[190] Despite this increased demand for folate, which must somehow be met by increased folate intake, the vast majority (over 90%) of pregnant women in resource-poor countries consume less than the estimated average requirement of folate[191]; in addition, a substantial number also consume less than optimum amounts of several other minerals, such as iron, and micronutrients, including cobalamin, as noted earlier. For example, studies on women from groups with low socioeconomic status from North India[32,33] have estimated that the daily intake of folic acid ranged between 75 and 167 μg, which is far lower than the 400 μg/day required to prevent birth defects.[68] This is simple to remedy by vigilant physicians. Indeed, when administered daily or even twice weekly, the combination of iron (100 mg elemental iron) and folic acid (0.5 mg) significantly improves several cognitive abilities of schoolgirls in India,[192] which renders them better prepared for pregnancy in the future. Not surprisingly, pregnancy with poor folate intake is the most common cause of megaloblastic anemia in resource-limited countries.

As noted earlier, the placenta has a large number of folate receptors,[68] which facilitate binding and transport of folates to the developing fetus. Preferential delivery of folate to the fetus can cause or aggravate folate deficiency in the mother.[16] This is observed clinically when a mother with severe folate deficiency gives birth to a baby who has normal folate stores.[67]

The rapidly proliferating tissues in children also have an absolute requirement for exogenously supplied folate. Although human milk of folate-replete mothers can maintain folate balance in breastfed infants, the breast milk content of folate is low when the mother's folate status is poor.

Before the advent of routine folate supplementation during pregnancy, the incidence of megaloblastic marrows in the United States, Canada, and the United Kingdom during late pregnancy was about 25%, but in South India, it was about 55%.[16] Folate deficiency is eight times as high in twin pregnancies. Multiparity (multiple frequent pregnancies with a prolonged state of negative folate balance) and hyperemesis gravidarum commonly lead to folate deficiency. When anemia of pregnancy is due to combined iron and folate deficiency, dimorphic anemia is the more frequent clinical presentation. Increased use of folates by the newborn leads to a drop in serum folate levels by about 6 weeks of age. This drop is exaggerated in premature infants (who have feeding difficulties, infection, or hemolytic disease leading to pure folate deficiency); hence supplementation is routine for them.[16]

Folates and Neurodevelopment

All inborn errors of folate metabolism, which result in reduced folate availability to the developing brain, give rise to mental retardation and related mental health problems. The fetal brain is dependent on sufficient provision of maternal folate during embryogenesis. Thus depending on the degree of maternal folate deficiency, there could be a spectrum of neurologic abnormalities; this could range from full-blown NTDs to more subtle changes that manifest in childhood as behavioral abnormalities.[60,72,193] Indeed, experimental studies in animals[60] indicate that folate deficiency significantly compromises early pregnancy outcomes (rates of pregnancy, rate of implantation, and effects on the number of live births). Even lesser degrees of folate deficiency to only one-third of optimum dietary folate—which mimics the extent of insufficient dietary folate availability among women in vast areas of Northern India[68]—results in increased apoptotic fetal brain loss (by 20%) and profound abnormalities in the white matter, reflecting perturbed neuronal development.[60] Surprisingly, despite postnatal folate replenishment, these mice exhibited an anxiety phenotype in adulthood[190]; in another study rodents exhibited learning problems.[194,195] In concordance with these studies in mice, human studies now consistently reveal that lower maternal folate status in early pregnancy is associated with psychological-neuropsychiatric disorders in childhood (hyperactivity/inattention and peer problems[196]; hearing loss[197]; learning deficits; children are emotionally reactive, anxious/depressed, have somatic complaints, withdrawn, with attention problems and aggressive behavior).[198–204] Thus women who take folic acid during the early stages of pregnancy provide an in utero environment that ultimately impacts positively on the child's intellect, emotional intelligence, cognition, language, and academic performance[200,201,205]; these observations are consistent with Barker's hypothesis on the developmental origins of disease.

As discussed above, the homocysteinylation of the mRNA-binding protein, hnRNP-E1, during folate deficiency orchestrates a nutrition-sensitive posttranscriptional RNA *operon* leading to

FOLATE-RESPONSIVE NEURAL-TUBE DEFECTS AND NEUROCRISTOPATHIES

NTDs are the most common major congenital malformation of the central nervous system. They arise from disturbances in neurulation that involve incomplete closure of neural tissues, leading to major midline defects. The neural tube, which begins as a tiny ribbon of tissue, normally folds inward to form a tube by the 28th day after conception. Thus NTDs originate in the first month of pregnancy (before many women know they are pregnant). Therefore, it is critical for a woman to have enough folate in her body before conception (periconceptionally) to ensure sufficient availability for the embryo. Anencephaly and spina bifida, the commonest NTDs, are important factors in fetal mortality (Fig. 40.10). Landmark studies have established the preventive role of periconceptional folates in both the *recurrence* of NTD (using folic acid 4000 μg/day) and the *first occurrence* of NTD (using a minimum of folic acid 400 μg/day).[206–208] Of significance, the greatest protection by folates occurs in those regions with the highest rates of NTDs.[209] Conversely, the use of folic acid antagonists (trimethoprim, triamterene, carbamazepine, phenytoin, phenobarbital, and primidone) during pregnancy increases the risk for these birth defects by twofold.[210]

Because 50% of pregnancies in the United States and elsewhere are unplanned and compliance with taking folic supplements to prevent NTD is only at about 50%, in January 1998, fortification of foods (i.e., rice, flour, pasta, macaroni, breads, and cake) with folic acid at 140 μg/100 g of food) was part of American law. This level was chosen to ensure that women of childbearing age would have an increase in folic acid intake of at least 100 μg a day, which is about 25% of the recommended daily intake. Subsequent evaluation has demonstrated that folate fortification of food has had multiple salutatory effects during human development and that major congenital abnormalities are prevented.[189] Table 40.5 shows several documented collateral benefits identified through population-based studies.

There remains concern about the effectiveness of the folic acid fortification program for women in the 15- to 35-year-old age group in preventing NTDs. This stems from an incomplete knowledge base[211] and their tendency to consume low-carbohydrate foods—the very foods that are fortified. This is the basis for recommendations to continue to educate women of childbearing age to take folic acid supplements at 400 μg/day (beyond what they receive through folate fortification of food).

Although regulations for mandatory fortification of wheat flour with folic acid are in place (in over 80 countries), they have not been uniformly implemented.[212] Moreover, folate-fortified foods do not reach all women of reproductive age adequately in resource-limited countries, particularly the most needy women in the lowest socioeconomic bracket.[213] As a result, over 90% of pregnant women worldwide still do not receive sufficient folate,[191] and over one-half of the world's population still does not have easy access to folate-fortified foods. As a consequence, in India, two population-based studies conducted a decade apart in the most populous state have identified that the incidence of NTDs was up to 8.21 and 7.48 per 1000 live births, respectively, which is still among the highest worldwide.[214,215]

Contrary to the American Dietetic Association's position paper on vegetarianism,[216] there is an insufficient body of evidence to confidently assert that women in the United States of childbearing age who consume a balanced vegetarian diet with abundant green leafy vegetables will obtain sufficient folate and therefore not be at risk for giving birth to babies with NTDs. Until robust evidence from clinical trials is available to support this Association's position paper,[216] a prudent approach is to recommend that all women who are vegetarians must take cobalamin and folate supplements.

TABLE 40.5 Beneficial Effects of Homocysteine-Lowering Therapy on Nonhematopoietic Systems

Using Folic Acid, Cobalamin, Pyridoxine Supplementation (Grade A Studies)
Reduction in hip fracture[293,a]
Reduction in the progression of carotid intima media thickness[294,a] (a surrogate marker of early subclinical arteriosclerosis)
Reduction in age-related macular degeneration[295,a]
Reduction in rate of brain atrophy[178,a]
Improvement in cognitive function[179,280,281,a]
Using Folic Acid Supplementation (Grade A Studies)
Reduction in stroke[291,a]
Reduction in the rate of cognitive decline among healthy older adults[279,a]
Reduction in age-related (sensorineural) hearing loss[292,a]
Reduction in first occurrence of NTDs[207,a]
Reduction in recurrence of NTDs[206,a]
Reduction in phenytoin-induced gingival hyperplasia[313,a]
Beneficial Effects of Folic Acid Fortification of Food (Population-Based Studies)
Reduction in NTDs[208,258] (anencephaly, spina bifida, encephalocele, meningocele, iniencephaly)
Reduction in cleft lip with or without cleft palate[314]
Reduction in severe congenital heart disease[258,314] (endocardial cushion defects, conotruncal defects)
Reduction in congenital pyloric stenosis, stenosis of the ureteropelvic junction, limb reduction defects[314]
Reduction in stroke mortality[315]
Decreased risk for preterm births, low birth weight, and small-for-gestational-age babies[316]

NTD, Neural-tube defect.

up- or down-regulation of several mRNA-derived proteins in murine brain.[62,64] There is now evidence that overexpression of one such mRNA member of this operon (encoding for neuronal intermediate neurofilament-middle molecular mass proteins) can perturb the integrity of myelin, whereas overexpression of another member, tyrosine hydroxylase mRNA, predicts for excessive generation of the key neurotransmitters (dopamine and norepinephrine) and disordered behavior.[62,64] (There may well be other proteins within the homocysteine-activated hnRNP-E1 operon that contribute to abnormal neurological dysfunction.) Such preclinical studies provide early mechanistic insight into how folate and cobalamin deficiency during pregnancy can influence fetal neurodevelopment and contribute to neuropsychological-neuropsychiatric disorders.[60,62,194] Indeed, it is possible that during folate deficiency, there may be a progressive homocysteine-mediated activation of many individual members of the wider hnRNP family within the developing brain. This, in turn, can trigger activation of the individual posttranscriptional RNA operons controlled by each of these hnRNPs, which, acting together in concert as a higher-order posttranscriptional RNA *regulon*, can profoundly affect fetal neurodevelopment.[62] Thus it appears that we are likely peering through the mist into an entirely new field, whereby nutritional folate insufficiency during fetal neurodevelopment can predispose to neuropsychiatric illness. (See box on Folate-Responsive Neural-Tube Defects and Neurocristopathies.)

Folates and Intrinsic Hematologic Disease

Because folate is necessary for hematopoiesis, folate requirements are increased when there is significant compensatory erythropoiesis in response to peripheral RBC destruction, abnormal hematopoiesis, or infiltration by abnormal cells in marrow. The recognition that folate deficiency developing in hemolytic disorders can lead to an acute aplastic crisis has long led to recommendations favoring routine prophylactic administration of folate. A meta-analysis of 19 studies has put to rest the concern of iron-folate and malarial progression[217] and a Cochrane analysis identified *no* evidence that this is a problem when combined with antimalarial drugs and insecticide-treated bed nets.[218,219] Sadly however, this dictum is not followed for most children living in malarial regions. An unexpected increase in transfusional requirement or a fall in platelets can also suggest folate deficiency.[16] The case of a patient with sickle cell disease on long-term folate who developed pernicious anemia and presented with neuropsychiatric dysfunction[220]

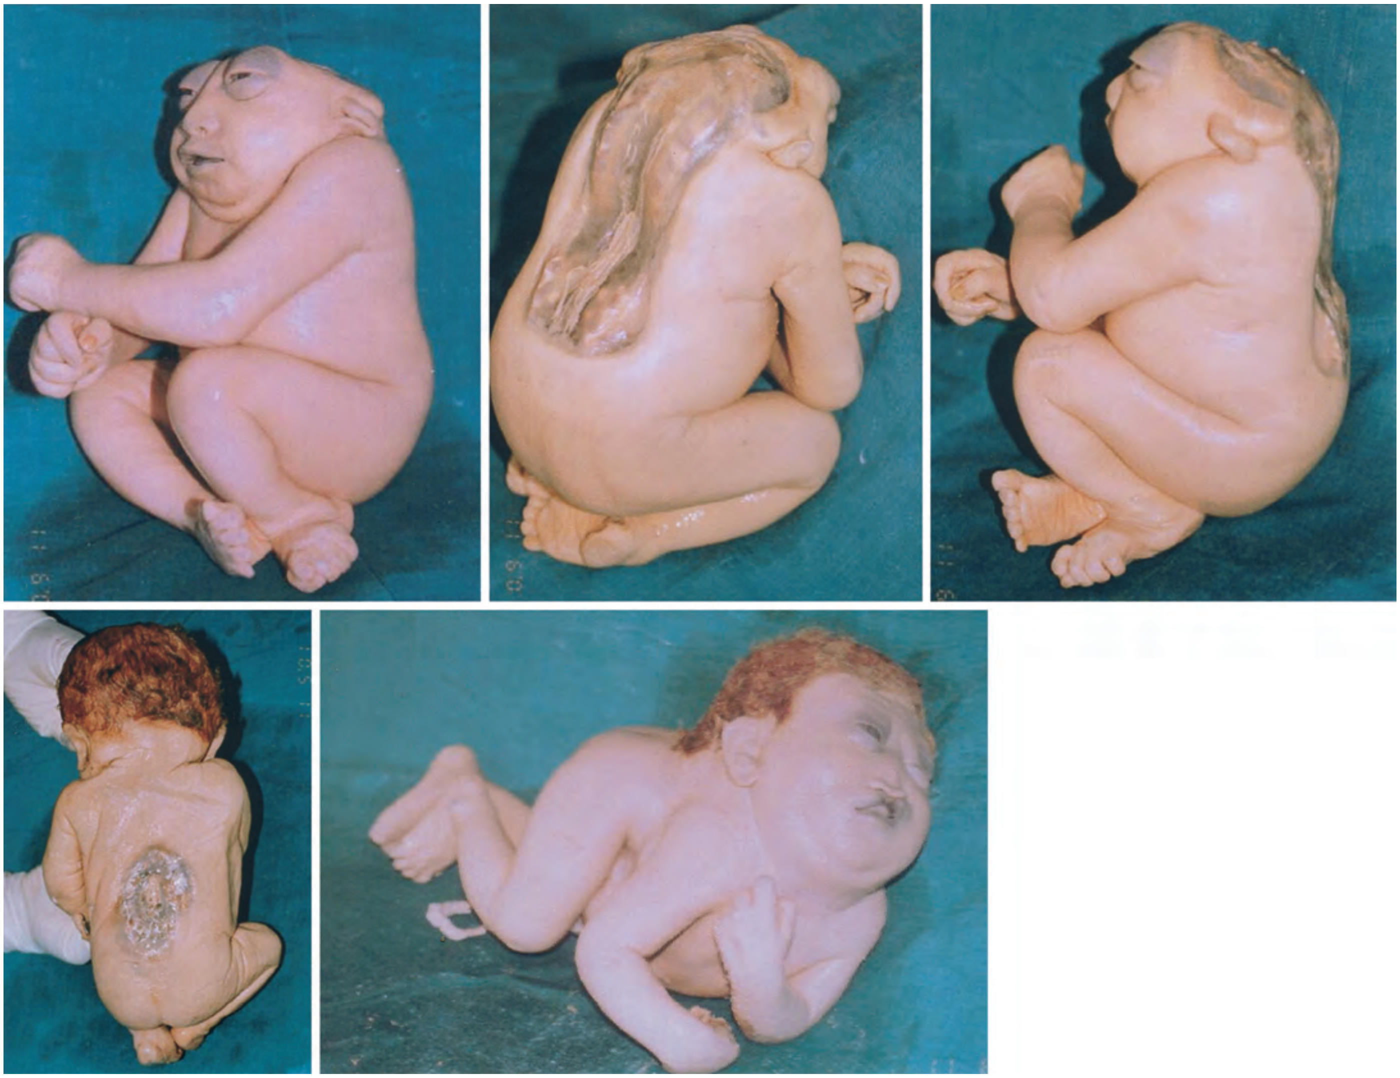

Figure 40.10 FOLATE-RESPONSIVE NEURAL-TUBE DEFECTS. Anencephaly with complete rachischisis *(top panel)*, open infected meningomyelocele *(bottom left)*, and iniencephaly with cleft lip *(bottom right*). *(Courtesy Prof. Molly Paul, Anatomy Department Museum, Christian Medical College and Brown Memorial Hospital, Ludhiana, Punjab, India.)*

is a valuable reminder that those on long-term folate prophylaxis need periodic follow-up for symptoms and signs of supervening cobalamin deficiency.

Folate Malabsorption With Normal Intestinal Mucosa

Hereditary Folate Malabsorption

Hereditary folate malabsorption, which is caused by loss of function mutations in the *PCFT* gene, was detected in approximately 35 different families (by 2015); in the USA, those of Puerto Rican descent share a common mutated allele.[221] Loss of PCFT is associated with inability to transport folate across the intestine and the choroid plexus and into the brain, resulting in low serum and CSF folate values with megaloblastic anemia, chronic diarrhea, and neurodevelopmental defects with seizures and mental retardation; this syndrome responds to high-dose parenteral folinic acid that bypasses and overcomes the transport defects. Affected patients can also present with a syndrome of reversible subacute combined immunodeficiency syndrome with hypogammaglobulinemia and recurrent infections.[222,223] If diagnosed early in infancy, hereditary folate malabsorption responds well to parenteral 5-formyltetrahydofolate and can allow normal development into adulthood.[218]

Folate Malabsorption With Intestinal Mucosal Abnormalities

Tropical Sprue

Residents of, and visitors to, endemic areas in the tropics can acquire a disorder characterized by small intestinal malabsorption.[16] Generalized, nonspecific small bowel malabsorption leads to a wide spectrum of clinical manifestations arising from defective absorption of fat, carbohydrate, albumin, calcium, folate, and in later stages, cobalamin.[16] There is abrupt onset of explosive, intermittent, or continuous diarrhea, abdominal distention, and pain, associated with anorexia, vomiting, and extreme fatigue. Stools are fluid or semisolid and frequently contain mucus and blood. This stage is followed weeks to months later by nutrient deficiency. Later, as steatorrhea continues, megaloblastosis dominates the clinical picture. In the short term, malabsorption leads to folate deficiency, but later in the chronic (longer than 3 years) phase of the disease, cobalamin malabsorption contributes additional clinical manifestations of cobalamin neuropathy.[16] There is some degree of villous atrophy and loss of intestinal functional surface. Although less severe than in nontropical sprue, it is more extensive, involving the entire small intestine.

After investigations for associated iron, cobalamin, and folate deficiencies, therapy with folate and a broad-spectrum antibiotic (e.g., tetracycline) is indicated together with symptomatic treatment of diarrhea and vomiting; fluid, mineral, and electrolyte imbalance; and other associated nutritional deficiencies.[16]

The dramatic response to folate and clinical response to antibiotics suggests a close interplay among a pathogenic infectious agent, endogenous flora, and the folate status of the enterocyte.

Nontropical Sprue

Nontropical sprue (i.e., celiac disease, gluten-induced enteropathy) is the most common cause of intestinal malabsorption in temperate zones. It results from a possibly inherited sensitivity to gluten (a glutamine-rich protein found in wheat, barley, rye, and other grains) and a related substance, gliadin.[16] The intestinal lesion (i.e., villous atrophy with hypertrophied crypts and lymphocytic and plasma cell infiltrate of the lamina propria) is more florid than that seen in tropical sprue but occurs to a greater extent in the proximal small intestine with relative ileal sparing; as a result, cobalamin malabsorption is less common. The consequences of malabsorption are otherwise the same. Patients present between the ages of 30 and 50 years with intermittent or persistent diarrhea (abrupt in 20%), weight loss, abdominal distention with discomfort, glossitis, and megaloblastic anemia. Iron deficiency is often prominent. Diagnosis is established by documenting the presence of sensitive and specific serum antiendomysial antibodies IgA type or anti-tissue transglutaminase antibodies, malabsorption, and jejunal biopsy. The megaloblastosis responds well to folate therapy.[16]

Regional Enteritis and Other Small Intestinal Disorders

The distal small intestine is involved in 80% of individuals with Crohn disease, so extensive ileal involvement or ileal bypass can result in malabsorption of cobalamin; the risk is twice as high with Crohn disease compared to ulcerative colitis.[224] However, a poor diet or extensive mucosal disease can increase requirements for folate[225] and the chronic use of sulfasalazine can interfere with the absorption of folates via interference with PCFT function.[45,226]

Cerebral Folate Deficiency

Cerebral folate deficiency is a broad syndrome whereby several diseases can be accompanied by neurologic findings with low CSF folate but normal serum folate levels.[227,228] The GPI-anchored folate receptor-α on the basolateral surface of choroid plexus cells is critical to the transport of folate from the blood across the CSF into the brain. Predictably, therefore, mutation of folate receptor-α, or the generation of antibodies to folate-binding proteins found in cow's milk that can cross-react with choroid plexus folate receptor-α, can perturb folate transport into the brain and lead to cerebral folate deficiency. Indeed, among a group of 14 children with extremely low (≤5 nmol/L) levels of 5-methyl-THF in the CSF, mutations in folate receptor-α, which led to a failure in expression of functional folate receptors, were identified in 10 of them (71%).[48,49] These children presented at less than 3 years with symptoms of developmental delay, movement disturbances, ataxia, myoclonic seizures, infantile spasms, and leukodystrophy that was reversed by folinic acid.[48,229] The finding of two older patients (aged 13 and 15 years) with severe polyneuropathy raises the possibility of other patients who may also have such defects that can present in young adulthood with unexplained neurologic disorders.

Acquired infantile-onset cerebral folate deficiency, which is associated with autoantibodies to folate receptor-α,[230,231] usually develops 4 to 6 months after birth and responds to high doses of folinic acid and a cow's milk–free diet.[232] Among 93 patients with autism spectrum disorders, 75% had autoantibodies to folate receptor in the serum; treatment with high-dose leucovorin led to improvement in one-third of those treated.[233] Of significance, an adult-onset presentation of cerebral folate deficiency with progressive memory loss and myoclonus caused by perturbation of folate receptor function by autoantibodies has also been described.[234] Finally, although anti-folate receptor antibodies are also associated with neural-tube defects,[78] infertility,[235] and orofacial clefts,[236] more information is required to confidently assign causality with these conditions.

Polymorphisms and Inborn Errors of Folate Metabolism

Several genetic polymorphisms involve genes that participate in one-carbon metabolism. These genetic polymorphisms merely reflect variants that are more frequent than the expected 1% allelic variation that could be found in any population. Whereas some polymorphisms impinge on normal physiology of folate and explain abnormal laboratory levels of folate, cobalamin, or metabolites, others may redistribute folate toward thymidylate synthesis and be "DNA protective." Predictably, two or more polymorphisms in the same individual (a combined heterozygote) can be associated with an increased risk for certain congenital diseases in offspring such as Down syndrome[237] or other birth defects. However, because disease association is not equivalent to disease causation, much more study is required to strengthen such relationships. A listing of the spectrum of these polymorphisms can be found in specialized texts.[238] Excellent reviews of inborn errors of folate metabolism are available.[163]

MEGALOBLASTIC ANEMIA NOT CAUSED BY FOLATE OR COBALAMIN DEFICIENCY

Several chemotherapeutic agents (e.g., antimetabolites, alkylating agents) kill malignant cells primarily by interfering with DNA synthesis; megaloblastosis is therefore an expected side effect. (See box on Miscellaneous Megaloblastic Anemias Not Caused by Cobalamin or Folate Deficiency.)

THERAPY

Routinely, treatment with full doses of parenteral cobalamin (1 mg/day) and oral folate (folic acid) (1 to 5 mg) before knowledge of the type of vitamin deficiency is established should be reserved for the severely ill patient. An appropriate regimen for conditions in which cobalamin replenishment can correct cellular cobalamin deficiency (but not correct the underlying problem that led to the deficiency, such as pernicious anemia) is 1 mg of intramuscular or subcutaneous cyanocobalamin per day (week 1), 1 mg twice weekly (week 2), 1 mg/week for 4 weeks, and then 1 mg per month for life (about 15%, or

MISCELLANEOUS MEGALOBLASTIC ANEMIAS NOT CAUSED BY COBALAMIN OR FOLATE DEFICIENCY

I. Congenital disorders of deoxyribonucleic acid (DNA) synthesis (rare)
  A. Orotic aciduria
  B. Lesch-Nyhan syndrome
  C. Congenital dyserythropoietic anemia
II. Acquired disorders of DNA synthesis
  A. Deficiency—thiamine-responsive megaloblastic anemia (thiamine transporter 1 mutation)
  B. Erythroleukemia, refractory sideroblastic anemias
  C. Drugs—any drug that inhibits DNA synthesis[119]
    - antinucleosides used as immunomodulators in autoimmune diseases
    - antineoplastics
    - antivirals against human immunodeficiency virus (HIV), hepatitis B/C, hantavirus, etc.
    - alcohol

DRUGS THAT PERTURB FOLATE METABOLISM[119]

Ethanol. Although beer has higher folate content than other alcoholic beverages, alcoholism may lead to neglect of healthy dietary practices in favor of alcohol. Alcohol consumption leads to a relatively rapid (2- to 4-day) fall in serum folate levels. Excess alcohol consumption is still a common cause of folate deficiency in the United States.[16]

Trimethoprim and *pyrimethamine* bind to bacterial and parasitic dihydrofolate reductase with much greater affinity than to human dihydrofolate reductase, but patients with underlying folate deficiency appear to be more susceptible to the effects of these drugs. The megaloblastosis can be reversed by folinic acid (5-formyl-tetrahydrofolate [5-formyl-THF]; leucovorin).[16]

Methotrexate binds with high affinity to human dihydrofolate reductase and leads to trapping of folate as a metabolically inert form (dihydrofolate). This leads to a true depletion of THF within hours and consequently to functional deficiency of 5,10-methylene-THF and reduced thymidylate synthesis. Although megaloblastosis can develop rapidly, the toxic effects of methotrexate can be avoided by rescue with 5-formyl-THF (leucovorin).[16]

Sulfasalazine produces megaloblastosis in up to two-thirds of patients taking full doses (over 2 g/day) by decreasing absorption of folates and induction of Heinz body hemolytic anemia thereby increasing requirements.[16]

Anticonvulsants can induce neural-tube defects (NTDs), and consensus guidelines have stressed the importance of ensuring that pregnant women[23] and children[239,240] with epilepsy be prescribed folates together with anticonvulsants. Whereas folates protect against spontaneous abortion,[241] folic acid supplementation of women receiving antiepileptic drugs also leads to a significant reduction of spontaneous abortion.[242] Phenytoin-induced gingival hyperplasia, which is a cosmetically undesirable side effect that affects a large percentage of patients, usually develops between 2 and 6 months of initiating therapy. A randomized controlled trial among children 6 to 15 years of age who were initiated on phenytoin has provided incontrovertible evidence that taking folic acid 0.5 mg daily can largely prevent phenytoin-induced gingival hyperplasia (whereas 88% in the placebo group developed gingival hyperplasia, only 21% in the folic acid group developed this side effect).[218] The data from this paper provide more “ammunition” to encourage young women on antiepileptic drugs to keep taking folic acid to prevent them from developing unsightly gingival hyperplasia—(particularly if reducing the risk for having a baby with NTD is too nebulous a concept for them). The only caveat is that before initiating long-term folic acid supplements, the cobalamin status must be normalized.

Although *antineoplastics, antiviral antinucleosides*, and *immunomodulators* can lead to megaloblastosis,[119] the temporal sequence and investigations to rule out cobalamin or folate deficiency should easily lead to a correct causal assignment.

CLINICAL PRESENTATIONS AND EVALUATION FOR FOLATE AND COBALAMIN DEFICIENCY

Clinical presentations and evaluations for folate and cobalamin deficiency are shown in Table 40.6.

The Interview

The patient’s general demeanor and answers to questions may reveal a blunted affect with evidence of depression, irritability, forgetfulness, and sleep deprivation (common in pure folate deficiency). Alternatively, cobalamin deficiency may present with paranoid ideation, dementia, cognitive dysfunction, delusions, or lack of energy manifested by slowed responses. Hallucinations or even obtundation may preclude obtaining an adequate history. The family may indicate the progressive evolution of a marked personality change and may be able to help trace the evolution of symptoms and deviations from the time when the patient was last well. Intermittent therapy with multivitamins, liver pills, or injections (often given by a well-meaning family member or unregistered practitioner) is a common quick fix in many cultures. Family members are a good source for details on the patient’s dietary habits (food faddism, vegetarianism, alcohol intake) and family history of medical problems (blood diseases, gluten sensitivity, autoimmune diseases).

A medical history of epilepsy or alcoholism with seizure disorder (anticonvulsant therapy) is important. Rarely, patients with autoimmune hemolytic anemias may be lost to follow-up and return with acute aplastic crises when they run out of folate. A surgical history of total or partial gastrectomy, anastomosis, fistula, or bowel resection can reveal the potential for perturbation of physiologic absorption (loss of intrinsic factor, bypassing or loss of absorptive surface, blind loop syndromes). Surreptitious or accidental inhalation of nitrous oxide in an occupational setting (dental or anesthesiology professionals) and deliberate inhalation of nitrous oxide using cartridges attached to whipped cream dispensers or visits to “houses of laughter,” where nitrous oxide can be inhaled for a small fee can be revealed only on direct questioning. Visits to tropical countries and the development of intermittent episodic diarrhea may give a clue to tropical sprue; prolonged (over 3 years) chronic gastrointestinal symptoms followed by insidious development of neurologic problems predicts a combined (folate followed by cobalamin) deficiency (see box on Drugs That Perturb Folate Metabolism).

Systemic review of symptoms may range from none (i.e., incidental increased mean corpuscular volume or PMN hypersegmentation) to severe (i.e., unstable angina from severe anemia). With slow development of anemia, the patient often does not develop cardiopulmonary symptoms until there is a 50% reduction in hemoglobin concentration, which leads to dyspnea on exertion, palpitation, and generalized fatigue or lethargy. Only when the hemoglobin concentration is below 5 g/dL does the patient develop dyspnea at rest and angina on modest exertion or even at rest. Congestive heart failure is heralded by pedal edema, nocturia, orthopnea, and tender hepatomegaly.

Upper gastrointestinal symptoms with anorexia associated with intrinsic gastrointestinal disease or anemia with heart failure must be distinguished from symptoms arising from aphthous ulcers or glossitis. The latter may lead to inability to wear dentures, or tolerate hot drinks or spicy foods because of burning, and even odynophagia, which may compromise further food intake (seen in cobalamin and folate deficiencies). The patient may volunteer that aphthous ulcers[243] or glossitis is relieved by vitamin B_{12} or multivitamin ingestion. Weight loss in cobalamin deficiency is not as severe as in folate deficiency arising from intrinsic gastrointestinal disease. Episodic or chronic diarrhea with steatorrhea is commonly caused by tropical sprue, although it may be brought on by gluten-containing foods. Although these symptoms may be accompanied by abdominal pain, pain in the absence of diarrhea could be caused by tabetic crisis (vomiting, abdominal rigidity, absence of leukocytosis, or fever) accompanying spinothalamic involvement in cobalamin-deficient myelopathy.

The patient with pernicious anemia may have two or three semisolid bowel movements per day; although this may be construed as a normal pattern, it may represent a change since the last time the patient was well. Constipation may be related to obstipation arising from involvement of the Meissner plexus and the Auerbach plexus within the gastrointestinal tract. Similarly, incipient loss of bladder or bowel control caused by cobalamin myelopathy may present with urgency or nocturia.

In contrast to musculoskeletal symptoms (arthralgia or frank arthritis) of autoimmune diseases, nocturnal cramps or pain in upper and lower extremities may indicate spinothalamic tract involvement. Hypoparathyroidism or systemic lupus erythematosus, alone or associated with pernicious anemia, leads to significant overlap of cerebral, musculoskeletal, and neurologic presentations.

Review of skin symptoms may elicit a history of increased diffuse or blotchy generalized brownish skin pigmentation, especially of nail beds and skin creases and knuckles. This is common in cobalamin deficiency; associated vitiligo suggests autoimmune disease.

Although symptoms related to neurologic dysfunction may be volunteered, a complete detailed questionnaire should be formulated during the interview. Questions should be directed to perversions in taste or smell, decreased visual acuity, changes in color vision, and eye pain (neuritis), tinnitus, or headache. Dizziness with orthostatic hypotension and “blacking out” may be related to severe anemia or cobalamin-deficient autonomic dysfunction, which can also be associated with night sweats.[244] Vertigo or difficulty in walking in the dark (loss of proprioception and position sense), difficulty in ambulation (which may feel like

CLINICAL PRESENTATIONS AND EVALUATION FOR FOLATE AND COBALAMIN DEFICIENCY—CONT'D

"walking on cotton wool"), stiffness of extremities (corticospinal tracts), or ataxia (spinocerebellar tracts) may be indicative of a serious cobalamin myelopathy. Early symptoms are symmetrical tingling ("pins and needles"), extending from the tips of the toes to a glove and stocking distribution in later stages. "Burning feet" syndrome, or more commonly, complaints of difficulty in performing simple tasks such as buttoning clothes, may also be a presenting symptom. When loss of bladder and bowel control brings the patient to the physician, advanced neurologic dysfunction is invariably present.

Genitourinary symptoms such as erectile dysfunction or recurrent cystitis from bladder dysfunction can suggest cobalamin neuropathy. Multiple pregnancies with short intervals between delivery and conception predispose to a high risk for overt folate deficiency and contribute to fetal growth restriction in babies (cobalamin deficiency is more often associated with infertility).

The Physical Examination

Physical examination may reveal different features in well-nourished patients (cobalamin-deficient vegetarians or pernicious anemia) and poorly nourished (folate-deficient) individuals. The latter show evidence of significant weight loss or other stigmata of multiple deficiencies because of either poor diet (malnutrition) or "broad-spectrum" malabsorption. Associated deficiency of vitamins A, D, and K and protein-calorie malnutrition may give rise to angular cheilosis, bleeding mucous membranes, dermatitis, osteomalacia, and chronic infections. Various degrees of pallor with lemon-tint icterus (i.e., a combination of pallor and icterus best observed in fair-skinned individuals) are common features of megaloblastosis.

When anemia is severe, the patient may have a low-grade fever. The skin may reveal a diffuse, brownish pigmentation or abnormal blotchy tanning.[245] A macular hyperpigmentation with follicular accentuation may be observed in the axilla and groin; hyperpigmentation can also involve the dorsal acral distal interphalangeal joints and a reticular pigmentation in the mid–upper back can develop slowly over a year (but resolves within 2 months of cobalamin replacement).[245] Special emphasis should be given to pigmentation of skin creases and nail beds and both palmar and dorsal aspects of hands and feet.[246] (Mucous membrane pigmentation is usually not observed, in contrast to Addison disease.) Premature graying, observed in light- and dark-haired individuals, is reversible within 6 months of cobalamin therapy.

A blunted mask-like facies is extremely common in folate deficiency. Alternatively, there may be evidence of classic hyperthyroid or hypothyroid facies (associated with pernicious anemia). Special attention should be given to the eyes and eyebrows for the well-known signs of thyroid dysfunction.

Examination of the mouth may reveal aphthous ulcers or glossitis with a smooth (depapillated), beefy red tongue with occasional ulceration of the lateral surface or gingival hyperplasia (antiepileptics). The neck may reveal thyromegaly (diffuse or with nodules) if there is associated disease. Increased jugular venous distention should alert the examiner to cardiovascular failure, with its attendant gallop, cardiomegaly (with or without pericardial effusions), pulmonary basal crepitations, pleural effusion, tender hepatomegaly, and pedal edema. Nontender hepatomegaly, but more often mild splenomegaly, may rarely be caused by extramedullary hematopoiesis in severe anemia, but a mid-epigastrium mass raises the ominous possibility of gastric carcinoma, which is up to seven times more likely[247] in patients with pernicious anemia.

In the West, an inverse correlation has been identified between the extent of anemia and neurologic dysfunction. Patients with normal complete blood count values often have neurologic signs and symptoms. In prolonged cobalamin deficiency, the neurologic examination reveals clear-cut evidence of involvement of posterior and pyramidal, spinocerebellar, and spinothalamic tracts. Among the earliest signs of posterior column dysfunction are loss of position sense in the index toes (before great toe involvement), which is elicited by passive movement, and loss of the ability to discern vibration of a high-pitched (256 cycles/s) tuning fork. This is a very early elicitable, objective sign, which invariably precedes by many months the loss of ability to sense the vibration of a lower-pitched (128 cycles/s) tuning fork. Usually the patient loses vibration sense to 256 cycles/s from toe to hip before loss of 128 cycles/s vibration sense even begins. Because of the slow coalescence of contiguous spinal cord lesions, a constellation of elicitable signs may be obtained. Upper motor neuron disease is indicated by weakness and progressive spasticity with increased muscle tone, exaggerated deep tendon reflexes with clonus, extensor plantar response, and incoordinate or scissor gait, which may progress to spastic paraplegia. The involvement of peripheral nerves may markedly modify these signs to include flaccidity and the absence of deep tendon reflexes. A positive Romberg sign is not uncommon, and a positive Lhermitte sign may be elicited. Loss of sphincter and bowel control, altered cranial nerve dysfunction with altered taste, smell, and visual acuity or color perception, and optic neuritis may be other physical signs indicating cobalamin deficiency. Inability to carry out serial subtraction of 7 from 100 is a valuable test to document reduced cerebral function (the electroencephalogram often reveals slow wave frequency) in pernicious anemia, which can progress over time to presentation with catatonia[248] or delirium (see box on Approach to Diagnosis and Therapy of Megaloblastosis and box on Practicing Classical Medicine Without the (Classical) Schilling Test.)[249]

APPROACH TO DIAGNOSIS AND THERAPY OF MEGALOBLASTOSIS

In general, there are three stages in approaching a patient: *recognizing* that megaloblastic anemia is present; *distinguishing* whether folate, cobalamin, or combined folate and cobalamin deficiencies have led to the anemia; and diagnosing the *underlying disease* and *mechanism* causing the deficiency. Establishing that the patient does have megaloblastosis is, in theory, straightforward. This is easily done by first evaluating the complete blood count, the mean corpuscular volume, and the peripheral smear; a bone marrow aspiration and biopsy is indicated if there is suspicion of another hematological disorder masquerading as a megaloblastic anemia (leukemia, myelodysplastic syndrome, aplastic anemia, etc.). Clues to whether cobalamin or folate deficiency is responsible for megaloblastosis can be obtained by serum cobalamin and serum folate levels; if these levels are borderline, additional testing of serum MMA and serum homocysteine can define the true nature of the deficiency.[23] However, this ideal and orderly workup is not always feasible in clinical practice, because the patient may present either for the first time with megaloblastosis with or without associated neurologic disease; or may be referred after a variable workup has already been initiated for possible megaloblastosis; or may present with symptoms primarily attributed to a disease predisposing to cobalamin or folate deficiency; or may present with a disease associated with hyperhomocysteinemia (discussed later), in which case anemia or neurologic dysfunction may only be a minor symptom; or may present with isolated neurologic disease in the absence of anemia; or may be referred after empirical therapy has been given for presumed cobalamin or folate deficiency. The immediate question therefore pertains to the overall status of the patient:

1. *If the patient is decompensated or decompensation is imminent*, obtain serum folate and cobalamin levels and freeze another serum sample in case metabolite testing is indicated later (i.e., if cobalamin and/or folate levels are equivocal). A bone marrow aspiration and biopsy should also be considered at this time (to confirm megaloblastosis or rule out another hematological disorder). Then proceed with transfusion of 1 unit of packed RBCs *slowly*, with vigorous diuretic therapy to obviate further congestive heart failure from fluid overload; this mandates the close monitoring and correction of fluid and electrolyte imbalance. Cobalamin and folate should also be administered simultaneously in full doses. Transfusion does not alter serum folate or cobalamin levels.
2. *If the patient is only mildly or moderately symptomatic* (but not likely to decompensate in the short term), proceed as above but withhold packed RBC transfusion. The strong likelihood of a dramatic response (in the sense of well-being and relief of sore tongue) within 2–3 days even before hematologic improvement argues against immediate blood transfusion.[23]
3. *If the patient is well compensated and is either in the hospital or in the outpatient setting*, the physician has time to develop an orderly

Continued

APPROACH TO DIAGNOSIS AND THERAPY OF MEGALOBLASTOSIS—CONT'D

sequence of diagnostic tests. First, check the peripheral smear and rule out other macrocytic anemias (thin macrocytes with a normoblastic marrow in contrast to macro-ovalocytes) (see Fig. 40.7). Draw blood for cobalamin and folate levels to sort out whether the problem is caused by a deficiency of folate or cobalamin, or both, or some other deficiency (see Table 40.2). The physician can elect to wait for the results of these tests before proceeding with the next test in the diagnostic workup.

If the serum cobalamin and folate levels are equivocal (i.e., in the low-normal range), then test for serum homocysteine and MMA. Integrating the results for serum MMA and homocysteine levels (which will be available after a week or more) with those for serum cobalamin and folate levels can help distinguish cobalamin and folate deficiencies (see Table 40.2). A normal MMA and homocysteine level eliminates cobalamin deficiency with 100% confidence, and normal homocysteine levels suggest that megaloblastic anemia is not caused by folate deficiency. These tests are particularly useful if the patient has pure neurologic disease or if there are associated conditions such as iron deficiency or thalassemia that can mask megaloblastosis. Administration of folate or cobalamin will reduce elevated serum homocysteine and MMA levels to basal values by 1 week,[48,175,221] so there is only a narrow window to clinch the diagnosis using metabolite tests.[23] In the rare situation when a hereditary defect in cobalamin or folate metabolism is suspected, early consultation with experts who have published in this area is advised.[20,48,175,176,221,250,251]

Additional supporting studies for megaloblastosis include reticulocytopenia, increased serum LDH, low haptoglobin, and increased bilirubin (evidence for intramedullary hemolysis).

Finally, try to determine the underlying mechanism of cobalamin or folate deficiency. The cause of folate deficiency is usually sorted out by this time from the history, physical examination, and the clinical setting. If pure folate deficiency has been prolonged, expect associated cobalamin deficiency to ensue (special emphasis should be given to identifying subtle manifestations of neurologic disease). If cobalamin deficiency is suspected, test for both serum anti-intrinsic factor antibodies and the newer more sensitive anti-parietal cell antibodies (see section on Pernicious Anemia.) Also see box on Practicing Classical Medicine Without the (Classical) Schilling Test.

TABLE 40.6 **Similarities of Clinical Manifestations and Megaloblastic Sequelae of Folate and Cobalamin Deficiency**[a]

System	Manifestations
Hematologic	Pancytopenia with megaloblastic marrow
Cardiopulmonary	Congestive heart failure
Gastrointestinal	Beefy-red tongue and added stigmata of broad-spectrum malabsorption in folate deficiency[b]
Dermatologic	Melanin pigmentation and premature graying
Genital	Cervical or uterine dysplasia
Reproductive	Infertility or sterility
Psychiatric	Depressed affect and cognitive dysfunction
Neuropsychiatric[c]	Unique to cobalamin deficiency with cerebral, myelopathic, or peripheral neuropathic disturbances, including optic and autonomic nerve dysfunction

[a] However, the neurologic spectrum of dysfunction in cobalamin deficiency is distinct. Inadequate hemoglobinization (from inadequate iron stores or globin synthesis) can mask the expected erythroid megaloblastic morphologic findings in the bone marrow and peripheral smear, and only specific therapy (i.e., iron) can unmask classic megaloblastic manifestations (i.e., masked megaloblastosis). Megaloblastic leukopoiesis is unchanged.

[b] If folate deficiency is uncorrected for 2–3 years, cobalamin deficiency will supervene.

[c] Dorsal tract involvement is earliest manifestation in more than 70% of patients with cobalamin deficiency. Neuropsychiatric manifestations are not associated with megaloblastosis in up to 30% of patients.

150 µg, is retained 48 hours after each 1 mg cobalamin injection).[16,23] *In principle, this protocol for rapid correction of cobalamin deficiency and complete replenishment of cobalamin stores should be used in the beginning for all patients with cobalamin deficiency, regardless of the etiology* (also see box above on Modified Therapeutic Trials).

Parenteral hydroxocobalamin is retained longer than cyanocobalamin and is widely used in Europe.[252] It is also reserved for all inborn errors of cobalamin metabolism. There is, however, no scientifically-proven major advantage of other preparations over generic cyanocobalamin in acquired cobalamin deficiency. There is equivalence between oral 2-mg cobalamin tablets consumed daily (where cobalamin is passively absorbed at high doses) and traditional monthly parenteral treatment with 1 mg of intramuscular/subcutaneous cobalamin among those requiring long-term cobalamin. So for patients who refuse monthly parenteral therapy, or prefer daily oral therapy, or in those with disorders of hemostasis, cobalamin (1 to 2 mg/day as tablets) can be recommended for all those patients with cobalamin malabsorption.[16,23,253] Alternative routes for cyanocobalamin delivery include nasal or sublingual preparations. The physician must ensure that the patient is compliant and demonstrates adequate cobalamin levels as well as resolution of hematologic and neurologic abnormalities on follow-up. For nutritional cobalamin deficiency (e.g., vegetarians) when the entire circuitry in cobalamin absorption is intact, after replenishing cobalamin stores with full doses, daily oral cobalamin of over 10 µg (found in conventional multivitamin tablets in the United States, or up to 50 to 150 µg tablets) taken for a lifetime of vegetarianism will suffice. However, if malabsorption of food-bound cobalamin is suspected (especially in the elderly with hypochlorhydria or achlorhydria), higher doses of daily oral cobalamin (equal to or greater than 1000 µg/day) is required.[254]

The bioavailability of oral cobalamin can be reduced by about 40% when it is taken with a meal; therefore, taking cobalamin on an empty stomach will lower losses in the stool. More than 98% of all the cobalamin in feces is in the form of cobalamin analogues, and about 80% of ingested food cobalamin is converted to analogues by microorganisms in the gut.[255]

Oral folate (folic acid) at doses of 1 to 5 mg/day results in adequate absorption (even where intestinal malabsorption of physiologic food folate is present). Therapy should be continued until complete hematologic recovery is documented. If the underlying cause leading to folate deficiency is not corrected, folate may be continued. Folinic acid (i.e., 5-formyl-THF [leucovorin]) should be reserved *only* for rescue protocols involving antifolates (methotrexate or trimethoprim-sulfamethoxazole), for 5-fluorouracil modulation protocols, after nitrous oxide toxicity, or in pediatric cases involving cerebral folate deficiency, hereditary folate malabsorption, or other inborn errors of folate metabolism. It is too expensive for conventional repletion in folate-deficient states in adults.

Response to Replenishment

The response of the patient to appropriate replacement is reversion of megaloblastic hematopoiesis to normal hematopoiesis within the first 12 hours; by 48 hours, normal hematopoiesis is reestablished, and the only evidence for a prior megaloblastic state may be the persistence of a few giant metamyelocytes. Clinically the first 36 to 48 hours are often highlighted by the awakening of an occasional semistuporous individual whose "chief complaint" is amazement at the remarkably improved sense of well-being experienced, with increased alertness and appetite, reduced soreness of the tongue, and healing aphthous ulcers.[243]

PRACTICING CLASSICAL MEDICINE WITHOUT THE (CLASSICAL) SCHILLING TEST

The Schilling test was used to identify the locus of cobalamin malabsorption and, in some instances, such as pernicious anemia or bacterial overgrowth, the cause of cobalamin deficiency. However, this test has been unavailable since 2003 in the United States. Although use of combined anti-IF antibodies and newer anti-parietal cell antibodies yields an overall 73% sensitivity while maintaining 100% specificity for pernicious anemia,[169] there remain difficulties in differentiating patients with all other causes of cobalamin malabsorption. A minimalist approach is to work around the unavailability of the Schilling test and use a classical clinical approach to rule out potential differential diagnoses of cobalamin deficiency (see box on Etiopathophysiologic Classification of Cobalamin Deficiency). For example, most conditions predisposing to cobalamin deficiency should be clinically manifest by the time cobalamin deficiency is evident. It should therefore be possible to identify several conditions through a detailed dietary history or past medical/surgical history, travel history, and drug history to suggest a nutritional deficiency, esophago-gastroduodenal disease, pancreatic insufficiency, impaired bowel motility, or other autoimmune diseases. The history and physical examination could provide further leads and suggest additional focused laboratory testing for rare conditions (stool for ova, anti–tissue transglutaminase antibodies, lipase, gastrin, intestinal biopsy, or radiographic contrast studies for stasis, strictures, fistulas). With no further leads, and therefore by default, one can assume that the diagnosis is either pernicious anemia or food-cobalamin malabsorption, which are both treated with similar replacement doses of cobalamin. For the younger patient with megaloblastic anemia, differentiating juvenile pernicious anemia and congenital IF deficiency would warrant measurement of gastric juice for IF and achlorhydria; DNA for gastric IF can identify hereditary megaloblastic anemia, and DNA for mutations in IF-cobalamin receptors (amnionless/cubilin genes) could identify Imerslund-Gräsbeck syndrome.

Thus the history, physical findings, and focused laboratory tests with careful clinical follow-up can potentially identify the cause of the majority of cases of cobalamin deficiency and bypass the need for a Schilling test.

Elevated serum MMA and homocysteine levels will return to normal in one week.

Accelerated turnover of normal DNA in erythroid precursors is associated with an increase in serum urate level, which usually peaks by the fourth day, and with increased cellular phosphate uptake for nucleotide synthesis. This may precipitate an attack of gout if the patient has a "gouty predisposition." The reticulocyte count increases by the second to third days and peaks by the fifth to eighth days (the peak reticulocyte count is directly proportional to the degree of preexisting anemia). This is followed by a rise in RBC count, hemoglobin, and hematocrit by the end of the first week, which normalizes in approximately 2 months, regardless of the initial degree of anemia. By the end of the third week, the RBC count should be above $3 \times 10^6/\text{mm}^3$; if it is not, additional causes of underlying iron deficiency, hemoglobinopathy, chronic disease, or hypothyroidism should be considered (Table 40.7).

Hypersegmented PMNs continue to remain in the blood for 10 to 14 days; however, the number of normal PMNs and platelets rises and normalizes within the first week. During this process, there may be a transient left shift to include myeloid precursors. The reduced intramedullary hemolysis (as a result of normalized hematopoiesis) leads to a gradual reduction in the serum bilirubin level by the end of the first week, and LDH levels will drop concomitantly.

In response to cobalamin, progression of neurologic damage and dysfunction is inhibited. In general, the degree of functional recovery is inversely related to the extent of disease and duration of signs and symptoms. As a rough estimate, signs and symptoms that have been present for less than 3 months are usually completely reversible; with longer duration, there is invariable residual neurologic dysfunction. The reversibility of neurologic damage is slow (a maximal response may take 6 months). Substantial increments (in recovery) are unlikely to be gained after the first 12 months of appropriate therapy. However, most neurologic abnormalities have improved in up to 90% of patients with documented subacute combined degeneration.

TABLE 40.7 Causes of Megaloblastosis Not Responding to Therapy With Cobalamin or Folate

Wrong Diagnosis
Combined folate and cobalamin deficiencies being treated with only one vitamin
Associated iron deficiency
Associated hemoglobinopathy (e.g., sickle cell disease, thalassemia)
Associated anemia of chronic disease
Associated hypothyroidism

Follow-Up

Patients with neurologic dysfunction from cobalamin deficiency have traditionally been given more frequent doses of cyanocobalamin (biweekly rather than monthly therapy for the first 6 months), despite the lack of evidence that this form of therapy is more beneficial. This approach nevertheless serves a purpose in that improvement in neurologic status can be carefully documented. Once maximal responses have been established, most patients can be treated with life-long cobalamin with a dose that is appropriate for the underlying cause of cobalamin deficiency. Follow-up outpatient visits every 6 months should be instituted to ensure adequate maintenance of hematopoiesis, as well as early diagnosis of other diseases commonly associated with the cobalamin- or folate-deficient state. Patients with pernicious anemia or food-cobalamin malabsorption are prone to developing iron deficiency that arises from poor iron absorption from achlorhydria and hypochlorhydria, respectively.[16,23] Therefore when iron deficiency is established, total dose replacement using parenteral iron, such as 1 gram of low-molecular-weight iron-dextran (INFeD) administered over an hour, is indicated.[256]

Patients with pernicious anemia have a twofold increase in proximal femur and vertebral fractures and a threefold increase in distal forearm fractures. The associated antral enterochromaffin cell hyperplasia (driven by hypergastrinemia that accompanies atrophic body gastritis) can be associated with dysplasia, a risk factor for development of neoplasia.[167] In addition, the loss of oxyntic glands and replacement by metaplastic pyloric or intestinal glands is a risk factor for gastric cancer.[167] Finally, three studies on nearly 15,000 patients with pernicious anemia have identified an excess risk for gastric cancers within the first few years of diagnosis,[257] so it is prudent to recommend upper endoscopy for these patients despite the lack of prospective data favoring this approach.

ROUTINE SUPPLEMENTATION OF COBALAMIN AND FOLATE

Routine periconceptional supplementation of folate for normal women[23] and in 10 times higher doses for women at risk for delivery of subsequent babies with NTDs[23] provides effective prophylaxis against the development of NTDs (Table 40.8); this also appears to reduce the risk for congenital heart disease,[258] and isolated cleft lip (with or without cleft palate) by about one-third.[259] Food fortification with folic acid (140 μg/100 g flour) has nearly eliminated folate deficiency[260]—the prevalence of low serum folate level decreased from 18.4% to 0.8% with a small (0.3 g/dL) increase in hemoglobin[261]; it has consistently reduced NTDs[208,209]; and is a cost-effective intervention,[262] particularly when additional supplementation is encouraged by physicians.[263] Despite fortification of wheat flour with folic acid in over 80 countries, in many instances, these are not rigorously

TABLE 40.8 **Indications for Prophylaxis With Cobalamin or Folate**

Prophylaxis With Cobalamin

Infants on specialized diets[a]

Premature infants

Infants of mothers with pernicious anemia[a]

Infants and children of mothers with nutritional cobalamin deficiency

Vegetarianism and poverty-imposed near-vegetarianism[a]

Total gastrectomy[b]

Prophylaxis With Folic Acid[c]

All women contemplating pregnancy (at least 400 μg/day)[d]

Pregnancy and lactation, premature infants

Mothers at risk for delivery of infants with neural-tube defects[e,f]

Hemolytic anemias/hyperproliferative hematologic states

Patients with rheumatoid arthritis or psoriasis on therapy with methotrexate[g]

Patients on antiepileptic drugs

Patients with ulcerative colitis

[a] For vegetarians, prophylaxis with cobalamin (5–10-μg tablet/day) orally should suffice. In all other conditions involving any abnormality of cobalamin absorption, cobalamin tablets of 1000 μg/day should be administered orally to ensure that cobalamin transport by passive diffusion across the intestine is sufficient to meet daily needs.

[b] Consider late development of cobalamin deficiency and iron malabsorption (prophylaxis with oral cobalamin and iron).

[c] Ensure that the patient does not have a cobalamin deficiency before initiating long-term folate prophylaxis.

[d] For prevention of first occurrence of neural tube defects.

[e] Previous delivery of a child with neural tube defects (e.g., anencephaly, spina bifida, meningocele) imparts a 10-fold greater risk for subsequent delivery of infant with neural tube defects.

[f] Folic acid (4 mg/day) administered periconceptionally and throughout the first trimester.

[g] To reduce toxicity of the antifolate.

implemented[212]; it is also not yet implemented in most highly populated resource-limited countries, resulting in over 90% of the world's women still vulnerable and without folate-fortified food.[191,213,264]

The administration of folate and cobalamin in addition to parenteral erythropoietin and iron to premature infants significantly improves hemoglobin values[16]; so this should be the standard of care.

Folate supplements during pregnancy also helps prevent premature delivery of low-birth-weight babies,[16] and routine supplementation for premature babies and lactating mothers is also recommended.

In addition to hematologic diseases leading to increased folate requirements (e.g., autoimmune hemolytic anemia, β-thalassemia, sickle cell disease), folic acid supplements reduce the hepatotoxicity and gastrointestinal intolerance of methotrexate in psoriasis[23,265] and rheumatoid arthritis[266] without impairing the efficacy of methotrexate.

For schoolchildren in resource-limited countries, simple community-level interventions, such as micronutrient fortification (using a premix added to school lunches), that build upon the infrastructure of an existing program have proven to be contextually acceptable and efficacious in improving folate and cobalamin (in addition to vitamin A and iron) status in Himalayan villages of India.[267] Table 40.8 summarizes conditions that warrant routine folate or cobalamin supplementation.

Following food fortification, the total folate intake of most US children 1 to 13 years of age does meet the estimated average requirement.[268] Whereas folic acid supplements consumed in excess of 1 mg/day can mask hematologic symptoms of cobalamin deficiency, it has been found that 94% of US adults who do not consume supplements, or who consume less than 400 μg of folic acid per day from supplements, do not exceed the upper limit in intake for folic acid.[269] There is still no unambiguous evidence that consumption of folate-fortified foods places individuals at risk for exacerbating any clinical manifestations of underlying cobalamin deficiency.[270] Indeed, a recent careful review of the historical record does not provide evidence that administration of folic acid can cause or aggravate neurological manifestations among subjects with cobalamin deficiency.[271]

In resource-limited countries, a strong case can be made to consider the fortification of flour (or other contextually relevant food vehicle) with small amounts of cobalamin and folate for the majority of the population whose dietary intake of animal-source foods is poor. This topic remains a work in progress. Likewise, immigrants from resource-limited countries will often continue to consume their native diet, which is usually low in animal-source foods, long after resettling in the United States[272]—as documented even among Indian physician trainees in New York![273] So these groups will also benefit from folate and cobalamin supplementation.

Although *Plasmodium falciparum* possesses folate transporter proteins that can facilitate membrane transport of folic acid and folinic acid,[274] the safety of using low-dose folic acid (1 mg/day) in 467 pregnant women with malaria has been affirmed[275]; however, high-dose folic acid (5 mg/day) can allow for *P. falciparum* resistance, with potential adverse outcomes in children.[276]

CHRONIC HYPERHOMOCYSTEINEMIA

Normally homocysteine is metabolized by the methylation reaction (discussed earlier) and by a second trans-sulfuration pathway, which essentially eliminates homocysteine as a potential source of methionine. In the trans-sulfuration pathway, cystathionine β-synthase catalyzes the condensation of homocysteine with serine in the presence of pyridoxyl phosphate (vitamin B_6) to form cystathionine, which is further cleaved by a vitamin B_6-dependent enzyme γ-cystathionase, to form cysteine and α-ketobutyrate. The cysteine that is formed can be used for synthesis of the antioxidant glutathione, a key component that defends against oxidative stress within cells. In some tissues like liver, homocysteine can also be remethylated to methionine by the transfer of a one-carbon moiety from betaine by the enzyme homocysteine methyltransferase, which is restricted to the liver and kidney. Thus the level of plasma homocysteine depends on genetically regulated levels of essential enzymes in one-carbon metabolism, the intake of folic acid or food folates, vitamin B_6, cobalamin, and other acquired conditions (dehydration, renal dysfunction, antifolates, and nitrous oxide exposure).

Chronic hyperhomocysteinemia is established as a major risk factor in occlusive vascular diseases, particularly increased small-vessel cerebrovascular disease–related strokes,[277,278] dementia, and Alzheimer disease.[279] Parenthetically, this is consistent with the observations that all inherited diseases involving a severe elevation of homocysteine are associated with cognitive deficit and poorer neurocognitive performance. And accelerated brain atrophy is often a characteristic among those with mild cognitive impairment who then go on to develop Alzheimer disease.[178,179,280,281] There have been three randomized controlled trials among elderly patients to suggest that homocysteine-lowering therapy can significantly slow down the accelerated rate of brain atrophy and improve cognition. Indeed, a recent consensus statement by a panel of experts concluded that elevated plasma total homocysteine is a modifiable risk factor for development of cognitive decline, dementia, and Alzheimer disease in older persons.[282] Chronic hyperhomocysteinemia is also a risk factor for reduced bone mineral density and increased incidence of fractures.[283,284]

Raised maternal plasma levels of homocysteine primarily from cobalamin and folate deficiency are associated with various pregnancy complications. These include preeclampsia and spontaneous pregnancy loss,[241,285–287] placental abruption,[285,286] recurrent pregnancy loss,[284–286] fetal growth restriction,[286,288] preterm birth,[289] and stillbirth.[288] The adverse outcomes for the baby include neural-tube defects and congenital malformations.[286,288] Normalization of maternal homocysteine level with cobalamin and folate and improvement of these pregnancy outcomes for some complications[284,286] indicate that some of these risks can be reduced with good nutrition.

FOLATE FORTIFICATION OF FOOD AND THE RISK FOR CANCER

Folate supplements protect the development of colorectal neoplasia in high-risk patients with ulcerative colitis.[23] Three large prospective studies[299–301] suggest that long-term folate intake actually *decreases the risk* for initiation or early development of colorectal cancer; in addition, there appears to be a diminished to nonexistent influence on (precancerous) adenomas. A meta-analysis of 13 randomized trials that compared the incidence of cancer of all types in ~50,000 individuals led to the conclusion that folic acid supplementation does not significantly increase or decrease the risk of cancer over a 5-year treatment period.[302] Collectively, these papers provide reassurance that the fortification of food to prevent neural-tube defects in women of childbearing age has not led to harm among the remaining "nontargeted" population of adults. There also could be long-term benefits in primary prevention (see Table 40.5). A cautious conclusion therefore is that clinical studies have still not unambiguously resolved whether or not folate supplements can actually prevent initiation of cancer or promote transformation of premalignant lesions to cancer.[303]

Homocysteine-Lowering Trials and Primary Versus Secondary Prevention

Most homocysteine-lowering intervention trials have been underpowered; they have looked at populations in which the serum homocysteine level has been borderline elevated rather than being elevated to the higher level (over 20 µM); and they have only had a follow-up of less than 5 years. Moreover, many of the intervention trials have been compromised by the advent of food fortification with folate or by enrolled patients who were consuming multivitamins containing folic acid. A review of this "homocysteine controversy"[290] has noted that the duration of follow-up in most studies has been too short (and likely dictated by the dramatic results from the use of antihypertensives and statins, which required only short follow-up to demonstrate positive effects). The point made is that such expectations are unrealistic for atherosclerosis because the atherosclerotic plaque commonly takes 30 to 40 years to develop into a full-blown clinical event. Moreover, there is a distinct difference between primary prevention of the earliest stages of a disease process and attempts to intervene after demonstrated vascular damage (secondary prevention). (Indeed, it was only longer follow-up for 10 to 15 years that established the primacy of blood glucose control in management of patients with diabetes.)

Thus despite the apparent failure of homocysteine-lowering therapy in several trials related to secondary prevention of atherosclerotic disease, this has *not* eliminated the possibility of a beneficial role of lowering homocysteine in primary prevention of diseases. Indeed, clinical trials have suggested that folate also has a role in reduction in strokes,[291] reduction in the rate of cognitive decline among healthy older adults,[280] and a reduction in age-related (sensorineural) hearing loss.[292] There is also Grade A evidence from randomized controlled trials for a role of folate in combination with cobalamin for reduction of hip fractures,[293] subclinical atherosclerosis,[294] and stroke prevention.[291] In addition, the value of a triple combination of folate, pyridoxine, and cobalamin to reduce age-related macular degeneration in women was shown by a relatively small study[295]; despite support by an observational epidemiology study,[296] larger studies are required (see Table 40.5).[297] *By inference, in addition to classical presentation with nutritional anemia, patients with long-standing hyperhomocysteinemia can also present with any of these additional clinical conditions, as well as a variety of pregnancy complications with or without poor pregnancy outcomes (affecting the newborn).*

One notable *exception* (to the value of homocysteine-lowering therapy) is in patients with diabetic nephropathy where such attempts *worsened* their kidney disease and placed them at greater risk for dying from serious vascular events.[298] (See box on Chronic Hyperhomocysteinemia and box on Folate Fortification of Food and Risk of Cancer.)

FUTURE DIRECTIONS

In this age of spiraling costs for health care delivery, and the ongoing debate on ways to reduce these costs, few instances in internal medicine and hematology yield more satisfying dividends than diagnosing and treating cobalamin and folate deficiency using generic vitamins that are "dirt cheap"—costing only a few cents a day. These conditions are devastating when undiagnosed or misdiagnosed or when cobalamin deficiency is treated with folate alone. Recognition of various populations at risk and the clinical scenarios in which folate and cobalamin deficiency are likely to be present, and the availability of sensitive and specific tests, should reduce uncertainty in diagnosis. The studies on folate supplementation during pregnancy that identified new folate-responsive NTDs and neurocristopathies are a paradigm for identification of hitherto unrecognized roles for other nutrients in human development. And the significant impact of supplemental folates in relieving human suffering consonant with reducing costs for intensive and long-term care of infants with prematurity or NTDs is a major achievement and an outstanding example of cost-effective preventive medicine. However, ensuring that *all* the world's women receive sufficient folate and cobalamin to break the cycle of vertical intergenerational deficiency in their progeny remains a critically important but still elusive goal. Other recent advances from randomized controlled studies indicate beneficial effects of supplemental folate and cobalamin in the prevention of diverse diseases. Folate receptor-α or -β targeting[304,305] using monoclonal antibodies against cancer or inflammation or various folate-tagged fluorescent probes,[306] newer radionuclides,[307] drugs, as well as ^{18}F-based folate radiotracers for positron emission tomography (PET) imaging,[308] are under intense scrutiny in the clinic. The influence of folates and cobalamin during development in utero—especially on behavioral neuroscience—allows us to peer into a new field where groundbreaking discoveries will be made in the coming decade. The new molecular links established between folate deficiency, homocysteinylated-hnRNP-E1, and its role in perturbing the HPV16 life cycle and HPV16-induced cancer, open the door to investigations into the potential role of these vitamins in the field of preventive oncology.[100,101] Finally, folate receptor-4 (renamed Juno after the Goddess of Fertility), which is found on the surface of eggs, is what the sperm protein, Izumo1 (named after a Japanese marriage shrine), recognizes and binds to gain entry and fuse to form a single diploid cell.[309] Further study of this pair of proteins raises the potential for identifying hitherto unrecognized fertility problems and the development of a new generation of contraceptives.[310] Collectively, these studies point to the profound spectrum of influence and the wealth of information that will be derived from continued study of these vitamins in physiology and medicine.

CHAPTER 41

THALASSEMIA SYNDROMES

Sujit Sheth

The thalassemia syndromes are a heterogeneous group of inherited anemias which result from defects in the synthesis of one or more of the globin chain subunits of the hemoglobin (Hb) tetramer. The basic defect, decreased or absent production of a globin subunit, results in an imbalance between globins produced as a result of expression of genes from the alpha-globin gene cluster on chromosome 16, and those produced from expression of genes on the beta-globin gene cluster on chromosome 11. As a result of the imbalance, there is ineffective erythropoiesis (IE) and defective red cell production. The spectrum of disease severity is determined by the degree of imbalance in globin chain production and varies from mild, with few clinical manifestations, to severe anemia and transfusion dependence.

The disease was first described by Cooley and Lee in 1925,[1] who coined the name Cooley's anemia to describe a severe anemia with splenomegaly and bony changes. The term *thalassemia* is derived from a Greek term that roughly means "the sea" (Mediterranean) in the blood.[2] It was first applied to the anemias frequently encountered in people from the Italian and Greek coasts and nearby islands, likely beta-thalassemia.[3–5] The term thalassemia is now used to refer to a wide range of inherited defects in globin-chain biosynthesis. The inheritance of the disease, and its wide spectrum of severity was described progressively over the last century as our understanding of the disease and its pathophysiology has grown. Discovered to arise from abnormalities affecting expression of the autosomal globin genes, the homozygous condition was termed thalassemia major to describe the most severe form of the disease, the heterozygous condition was termed thalassemia minor or minima to describe a mostly asymptomatic carrier state, and the compound heterozygous states—somewhere in between—were called thalassemia intermedia.

The thalassemias are the commonest monogenic disorders in humans, and have a wide distribution across the globe. Approximately 1.5% of the world's population carries one of the globin gene mutations, the majority of these individuals living in Asia, in areas of the world where thalassemia is particularly prevalent. It comprises a major public health problem. The main thalassemia syndromes are broadly alpha (α)-thalassemia and beta (β)-thalassemia, the clinical manifestations and morbidity of which vary based on the genotype and other modifying factors such as access to care and therapy-related complications, particularly iron overload.

This chapter reviews the major features of these syndromes. Readers wanting more detailed information than can be included here are referred to more comprehensive monographs elsewhere.[2,6]

DEFINITIONS AND NOMENCLATURE

The most common forms of thalassemia arise from total absence of structurally normal globin chains or a partial reduction in their synthesis. In contrast to the "structural" hemoglobinopathies (e.g., sickle cell anemia), which are characterized by the production of normal amounts of mutant globin chains having abnormal physical or chemical properties, the thalassemias are quantitative disorders: the primary defects lie in the amount of globin produced. However, some forms of thalassemia are characterized by the production of structurally abnormal globin chains in reduced amounts, which are described in more detail in this chapter. These thalassemic hemoglobinopathies share features of thalassemia as well as those of structural hemoglobinopathies.[7]

Individual syndromes are named according to the globin chain whose synthesis is adversely affected. Thus, α-globin chains are absent or reduced in patients with α-thalassemia, β-globin chains in patients with β-thalassemia, δ-globin and β-globin chains in patients with δβ-thalassemia, and so forth. In some contexts, it is also useful to subclassify the syndromes according to whether synthesis of the affected globin chain is totally absent (e.g., β^0-thalassemia) or only partially reduced (e.g., β^+-thalassemia).

Some mutations alter the patterns of fetal to adult Hb switching. These conditions, called *hereditary persistence of fetal hemoglobin*, are not generally associated with clinical symptoms; nonetheless, they merit consideration in this chapter. Their importance lies in their role as modulating factors when coinherited with other hemoglobinopathies. They are also useful models for investigating the molecular basis for globin gene regulation during human development and as paradigms for rational therapy for the major β-chain hemoglobinopathies, namely, sickle cell anemia and β-thalassemia.

EPIDEMIOLOGY

Thalassemias have been encountered in virtually every ethnic group and geographic location. They are most common in the Mediterranean basin and tropical or subtropical regions of Asia and Africa. The "thalassemia belt" extends along the shores of the Mediterranean, through the Arabian peninsula, Turkey, Iran, India, and southeastern Asia, especially Thailand, Cambodia, and southern China.[8–11] The prevalence of carriers of thalassemia in these regions is in the range of 2.5% to 15%. Similar to sickle cell anemia, thalassemia is most common in areas historically affected by endemic malaria. Malaria seems to have conferred selective survival advantage to thalassemia heterozygotes in which infection with the malarial parasite is believed to result in milder disease and less impact on reproductive fitness.[2,6,12] Therefore, the gene frequency for thalassemia has become fixed and high in populations exposed to malaria over many centuries. Migration from these parts to the rest of the world has resulted in the thalassemias being found all over the world, including Australia and the Americas, though β-thalassemia is still somewhat uncommon in Africa, except parts of West Africa and North Africa bordering on the Mediterranean Sea. The most severe form of α-thalassemia is found mainly in the Oriental populations because of the higher prevalence of the two gene deletions in *cis* configuration in these areas.

PATHOPHYSIOLOGY: GENERAL PRINCIPLES

The classification, genetic basis, and pathophysiology of the thalassemia syndromes are based on a thorough understanding of the human hemoglobins, their biosynthesis, their encoding *globin* gene families, and their roles as soluble oxygen-carrying molecules. Therefore, readers of this chapter should first familiarize themselves with the material presented in Chapter 34. The material presented in this chapter is also substantially clarified by prior reading of Chapters 35, 36, and 37 because the principles underlying the pathophysiology of and therapy for thalassemia draw heavily on knowledge of iron metabolism.

The primary lesion in all forms of thalassemia is reduced or absent production of one or more globin chains. Red blood cells (RBCs) contain a mix of hemoglobin types, which vary through intrauterine development. These molecules have the same heme moieties but differ in globin chains. In the post-natal period, after infancy, the predominant hemoglobin is adult hemoglobin or HbA, a heterodimer of 2 alpha and 2 beta globins ($\alpha_2\beta_2$). For all practical purposes, the major impact on clinical well-being occurs only when these lesions affect the α- or β-globin chains necessary for the synthesis of adult Hb. Severe impairment of γ-, ε-, or ζ-globin production is presumably lethal in utero, and has not been observed in human biology.

One consequence of reduced globin-chain production is immediately apparent: reduced production of functioning Hb tetramers, and consequently anemia. Thus, hypochromia and microcytosis are characteristic of virtually all patients with thalassemia. In the mildest forms of the disease, this phenomenon may be barely detectable.

The second consequence of impaired globin biosynthesis is unbalanced synthesis of the individual α- and β-subunits. Hb tetramers are highly soluble and have reversible oxygen-carrying properties exquisitely adapted for oxygen transport and delivery under physiologic conditions. Free or "unpaired" α-, β-, and γ-globin chains are either highly insoluble ("unstable") or form homotetramers of alpha-globin (Fessas bodies), beta-globin (HbH), or gamma-globin (Hb Bart), that are incapable of releasing oxygen normally, and because they are relatively unstable, will precipitate as the cell ages. For poorly understood reasons, no compensatory regulatory mechanism exists whereby impaired synthesis of one globin subunit leads to a compensatory downward adjustment in the production of the other (partner) globin chain of the Hb tetramer. Thus, useless excess α-globin chains continue to accumulate and precipitate in red cell precursors in β-thalassemia, and excess β-globin chains form HbH in α-thalassemia. The abnormal solubility and oxygen-carrying properties of these chains lead to a variety of physiologic derangements. Indeed, in the severe forms of thalassemia, it is the behavior of the unpaired globin chains accumulating in relative excess that dominate the pathophysiology of the syndrome rather than the mere underproduction of functioning Hb tetramers. The precise complications of this pathophysiologic phenomenon are diverse and depend on the amount and the identity of the globin chain accumulating in excess.

The predominant pathophysiologic determinant in α-thalassemia is the production of HbH, with anemia and impaired oxygen carrying capacity, while in β-thalassemia it is apoptosis of the erythroid precursors in the bone marrow (BM) as a result of hemichrome formation from precipitation of alpha globin aggregates. Thus, IE, while part of both, is more severe when there is an excess of α-globin in β-thalassemia, compared with a similar degree of β-globin excess in α-thalassemia, making the pathophysiology of anemia quite different.

The predominant circulating Hb at the moment of birth is fetal hemoglobin (HbF, $\alpha^2\gamma^2$). Although the switch from γ- to β-globin biosynthesis begins before birth, the composition of Hb in the peripheral blood changes much later because of the long-life span of normal circulating RBCs. HbF is thus slowly replaced by HbA so that infants do not depend heavily on normal amounts and function of HbA until they are between 4 and 6 months old. The pathophysiologic consequences of these considerations are that whereas α-chain hemoglobinopathies tend to be symptomatic in utero and at birth, individuals with β-chain abnormalities are not very symptomatic until 4 to 6 months of age. These differences in the onset of phenotypic expression arise because α-chains are needed to form HbF and HbA, but β-chains are required only for HbA. Red cells which continue to produce gamma globin will have a selective survival advantage in β-thalassemia because they reduce the imbalance from excess α-globin.

BETA-THALASSEMIA SYNDROMES

Nomenclature

Approximately 350 mutations in the beta-globin gene cluster have been described. These mutations vary widely in severity, from complete non-production of beta-globin, called beta-zero (β^0), some expression and thus some production of beta-globin (β^+), to the production of abnormal beta-globins which result in abnormal hemoglobins such as HbE (β^E). There is, thus, considerable phenotypic variability in these syndromes. The most severe form was termed thalassemia major, and referred to a clinically severe disease with marked IE and its manifestations, severe anemia, lifelong transfusion dependence, complications mostly related to iron overload, and a shortened life expectancy. The genotype is typically, but not exclusively, β^0/β^0 or β^0/β^+. At the other end of the spectrum is thalassemia minor which refers to the trait, or carrier state, with one normal β-globin gene, either β/β^0 or β/β^+. In between is a broad spectrum of disease referred to as thalassemia intermedia, which is milder, with a moderate anemia which may not require regular transfusions, with more complications from IE and hemolysis than iron overload, mostly related to skeletal changes and vascular disease. Beta-globin genotypes which result in this clinical syndrome include, but are not limited to, β^0/β^+, β^+/β^+, β^0/β^E or β^+/β^E. A number of more complex genotypes may also be implicated, such as the delta-beta-thalassemias $(\delta\beta)^+$, or hemoglobin Lepore $(\delta\beta)^0$, or $({}^A\gamma\delta\beta)^0$, a single β-thalassemia defect and an excess of normal alpha-globin genes, or two β-thalassemia mutations coinherited with heterozygous α-thalassemia (in this last form, known as αβ-thalassemia, the α-thalassemia allele reduces the burden of unpaired α-chains).[13–15] Simple heterozygosity for certain forms of β-thalassemic hemoglobinopathies can also be associated with a thalassemia intermedia phenotype, sometimes called *dominant β-thalassemia*.[16,17]

Terminology based on the clinical spectrum of disease previously focused on the need for regular transfusions early in life, with those individuals being classified as thalassemia major. Those who did not require regular transfusions but had other manifestations of the disease were referred to as having thalassemia intermedia. However, in the course of their disease many individuals who were initially not regularly transfused could come to need regular transfusions, and thus move along the spectrum from intermedia to major. Currently, the trend has been to simply classify patients as having transfusion-dependent thalassemia (TDT) if they are regularly transfused (requiring 8 or more transfusions per year), or non-transfusion-dependent thalassemia (NTDT) who may or may not require intermittent transfusions.

Molecular Pathology

Forms of β-thalassemia arise from mutations that affect every step in the pathway of globin gene expression: transcription, processing of the messenger ribonucleic acid (mRNA) precursor, translation of mature mRNA, and posttranslational integrity of the β-polypeptide chain (Fig. 41.1 and Table 41.1).[18–20] Large deletions removing two or more non–β-genes are found in rare cases, as are smaller partial or total deletions of the β-gene alone (see Fig. 41.1). Most types of β-thalassemia are caused by point mutations affecting one or a few bases.[18–24] Of the more than 200 mutations causing β-thalassemia, approximately 15 account for the vast majority of affected patients, with the remainder responsible for the disorder in only relatively few patients. It has been determined that five or six mutations usually account for more than 90% of the cases of β-thalassemia in a given ethnic group or geographic area (see Table 41.1).[21]

Several mutations alter the promoter region upstream of the β-globin mRNA-encoding sequence, impairing mRNA synthesis. Mutations in the upstream "master switch" or "LCR" sequences that are needed to induce the high rate of β-globin expression also lead to inadequate production of globin mRNA, while mutations

	IVS-2, position 1 (G → A)
African	−34 (A → G)
	−88 (C → T)
	Poly(A), (AATAAA → AACAAA)
Southeast Asian	Codons 41/42, frameshift (-CTTT)
	IVS-2, position 654 (C → T)
	−28 (A → T)
Asian Indian	IVS-1, position 5 (G → C)
	619-bp deletion
	Codons 8/9, frameshift (++G)
	Codons 41/42, frameshift (−CTTT)
	IVS-1, position 1 (G → T)

Data from Kazazian HH Jr, Boehm CD. Molecular basis and prenatal diagnosis of beta-thalassemia. *Blood*. 1988;72(4):1107. https://pubmed.ncbi.nlm.nih.gov/23637309/

that derange the sequence used as the signal for the addition of the poly-(A) tail of the mRNA polyadenylation signal have been shown to result in abnormal cleavage and polyadenylation of the nascent mRNA precursor, with resulting reduced accumulation of mature mRNA.[18–20]

Processing

Many forms of β-thalassemia are caused by mutations that impair splicing of the mRNA precursor into mature mRNA in the nucleus or that prevent translation of the mRNA in the cytoplasm. The molecular pathology of splicing mutations is complex (Fig. 41.2). Some base substitutions ablate the donor (GT) or acceptor (AG) dinucleotides, which are absolutely required at the intron–exon boundaries for normal splicing and thereby completely block production of mature

Figure 41.2 β+-THALASSEMIA ARISING FROM ALTERNATIVE MRNA SPLICING CAUSED BY A MUTATION ACTIVATING A CRYPTIC SPLICING SITE. (A) The G→A mutation is shown enclosed in *squares* located near the 3′ end of intron 1 (IVS-1); it creates a sequence motif closely mimicking a pre-mRNA acceptor splice site. The product of the alternative splicing event is also shown. Note that use of the activated cryptic site generates a mature mRNA that contains an in-frame termination codon and therefore does not encode a functional β-globin chain. (B) Diagram of the means by which use of the cryptic splice site 90% of the time results in only 10% of the mRNA precursor molecules to be spliced normally into translatable mature mRNA, thus causing β+-thalassemia. *mRNA*, Messenger ribonucleic acid. *((A) From Benz EJ Jr. The hemoglobinopathies. Philadelphia: WB Saunders; 1986.)*

functional messenger RNA. Thus, no β-globin can be synthesized (β^0-thalassemia). Other mutations alter the consensus sequences that surround the GT- and AG-invariant dinucleotides and decrease the efficiency of normal splicing signals by 70% to 95%, resulting in β$^+$-thalassemia; some consensus mutations even abolish splicing completely, causing β°-thalassemia. A third type of splicing aberration results from mutations that are not in the immediate vicinity of a normal splice site. These alter regions within the gene, called *cryptic splice sites*, which resemble consensus splicing sites but do not normally sustain splicing (see Fig. 41.2). The mutations activate the site by supplying a critical GT or AG nucleotide or by creating a sufficiently strong consensus signal to stimulate splicing at that site 60% to 100% of the time. The activated cryptic sites usually generate an abnormally spliced, untranslatable mRNA species. Only 10% to 40% of the mRNA precursors are thus spliced at the normal sites, which causes β$^+$-thalassemia of variable severity. The mutation responsible for the most common form of β-thalassemia among Greeks and Cypriots (Fig. 41.3) activates a cryptic splice site near the 3′ end of the first intron (position 110).[25,26] The determinants that dictate the degree to which each mutation alters splice site use remain largely unknown.

Translation

Mutations that abolish translation occur at several locations along the mature mRNA and are very common causes of β-thalassemia (see Fig. 41.1 and Table 41.1). The most common form of β°-thalassemia in Sardinians results from a base substitution in the gene that changes the codon encoding the 39th amino acid of the β-globin chain from CAG, which encodes glutamine to TAG, whose equivalent (UAG) in mRNA specifies termination of translation (see Fig. 41.3).[27,28] A premature termination codon totally abrogates the ability of the mRNA to be translated into normal β-globin. Premature translation termination also results indirectly from frameshift mutations (i.e., small insertions or deletions of a few bases, other than multiples of three, that alter the phase or frame in which the nucleotide sequence is read during translation).[28] An in-phase premature termination codon is usually encountered within the next 50 bases downstream from a frameshift.

Other Sites

Rare mutations that affect gene function by intriguing mechanisms have been described. An extremely large deletion of the β-globin gene cluster has been described that removes the ε-, γ-, and δ-genes.[29] The patient has a severe β-thalassemia phenotype, but the β-globin gene and 500 bases of adjacent 5′ and 3′ DNA have an entirely normal nucleotide sequence. The β-gene functions normally in surrogate cells. The important aspect of this deletion is that it removes the critical locus control region located thousands of bases upstream from the beginning of the globin gene cluster at the 5′ end of the ε-globin gene; loss of this region severely impairs β-gene expression.[18,30] A number of additional deletions involving the locus control region and various portions of the β-gene cluster, but sparing the β-gene itself, have the same phenotype.[2,6,18–20]

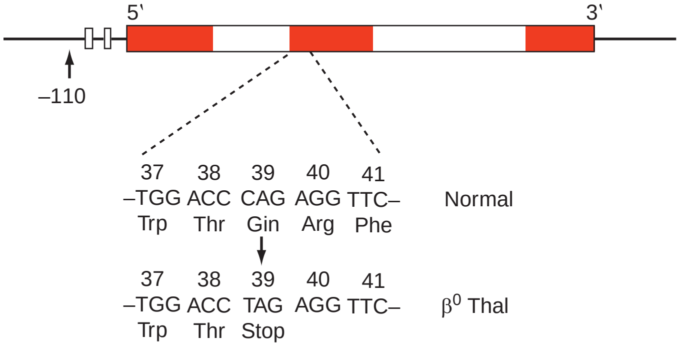

Figure 41.3 β^0-THALASSEMIA ARISING FROM A MUTATION CHANGING AN AMINO ACID CODON TO A TERMINATION CODON (NONSENSE MUTATION). *(Adapted from Takeshita K, Forget BG, Scarpa A, Benz EJ Jr. Intranuclear defects in β-globin mRNA accumulation due to a premature translation termination codon. Blood. 1984;64:13.)*

In other cases of β-thalassemia, the β-gene and adjacent DNA are structurally normal, and the basis of abnormal gene expression is unknown.[21]

Relationship Between Specific Mutations and Clinical Severity

The relationship between an individual mutation and the clinical severity of the β-thalassemia phenotype associated with that particular mutation is complex.[21] For example, the A to G mutation at position 34 of the β-gene promoter commonly encountered in patients of African origin is associated with a different clinical severity than that found in Chinese patients inheriting the same mutation.[31] Clearly, the genetic "context" of the mutation is different in the two populations. The mutant β-globin gene in the two different racial groups probably arose in different chromosome backgrounds that have different potentials for γ-gene expression. Multiple forms, or haplotypes, of normal non–α-globin gene clusters exist in various human populations. These were defined by the patterns of restriction fragment length polymorphisms detected when DNA is digested with restriction endonucleases and analyzed by Southern gene blotting for the fragments bearing the non–α-globin genes.[27] The gene cluster is now readily analyzed by direct genomic sequencing. Haplotypes differ according to whether each restriction site is present or absent along the gene cluster. More than 12 haplotypes have been defined by examination of several restriction sites located along the cluster that are present or absent in a polymorphic manner in normal individuals.[27] The clinical variability encountered in two different groups bearing identical primary mutations correlates best with the haplotype or chromosome background on which the mutation is inherited. The differences in physiologically important functions among haplotypes that modulate severity remain unknown, but a possible explanation lies in the variable abilities of the γ-globin genes on different chromosomes to respond to severe erythroid stress by increased expression during postnatal life. The β-globin genes carried on some haplotypes differ in the degree to which they can respond in this manner.[32] Because HbF synthesis reduces the severity of β-chain hemoglobinopathies,[2] the level of γ-gene expression from a given chromosome can play an important modulating role.

Pathophysiology

Erythropoiesis is essentially a two-phase process, erythropoietin (EPO) driving the initial proliferative phase, leading to stimulation of the stem cell toward the erythroid lineage, and proliferation through the BFU-E and CFU-E phases. The second stage is one of differentiation and maturation, with the proerythroblasts moving through the different erythroblast phases, into reticulocytes and eventually mature red cells (Fig. 41.4).

As described, the basic molecular abnormality in β-thalassemia is the imbalance between alpha and beta globin production, with reduction in beta globin production and thus a decrease in HbA ($\alpha_2\beta_2$) production. The ratio of β- to α-globin is typically close to 1. When abnormal, this ratio has a direct correlation with clinical severity in β-thalassemia patients.[33] In β-thalassemia heterozygotes, β-globin synthesis is approximately half-normal, with the ratio of β- to α-chain mRNA (β/α ratio) of 0.5 to 0.7 (normal = 1.0). In homozygotes for β^0-thalassemia, which account for approximately one-third of patients, β-globin synthesis is absent. β-globin synthesis is reduced

to 5% to 30% of normal levels in β^+-thalassemia homozygotes or β^+/β°-thalassemia compound heterozygotes, which together account for approximately two-thirds of cases.[2] The excess α-globin chains may be stabilized by alpha Hb stabilizing protein, which is a chaperone-like protein that assists in binding free α-globin chains. Higher levels of alpha Hb stabilizing protein result in more IE, and thus a more severe clinical phenotype.[33]

The decreased or absent synthesis of HbA ($\alpha_2\beta_2$) results in the production of smaller red cells and depending on the severity of the deficiency, hypochromia as well. RBCs are always microcytic in the thalassemias across the spectrum, and usually hypochromic though not so much in heterozygotes. γ-Chain synthesis is partially reactivated, and there is some upregulation of δ chain synthesis, though not enough to replace the deficiency of β-chains, and thus the red cells may contain relatively large proportions of HbF ($\alpha_2\gamma_2$) and some HbA2 ($\alpha_2\delta_2$).[2]

Individuals inheriting two β-thalassemic alleles experience a more profound deficit of β-chain production. Little or no HbA is produced, and importantly, the imbalance of α- and β-globin production is far more severe (Fig. 41.5). In the BM, the limited capacity of the red cell precursors to proteolyze the excess α-globin chains, a capacity that probably exerts a protective effect in heterozygous β-thalassemia, is overwhelmed in homozygotes. Free α-globin accumulates, and unpaired α-chains aggregate and precipitate to form inclusions called Fessas bodies and hemichromes with the addition of heme iron, which cause oxidative membrane damage leading to

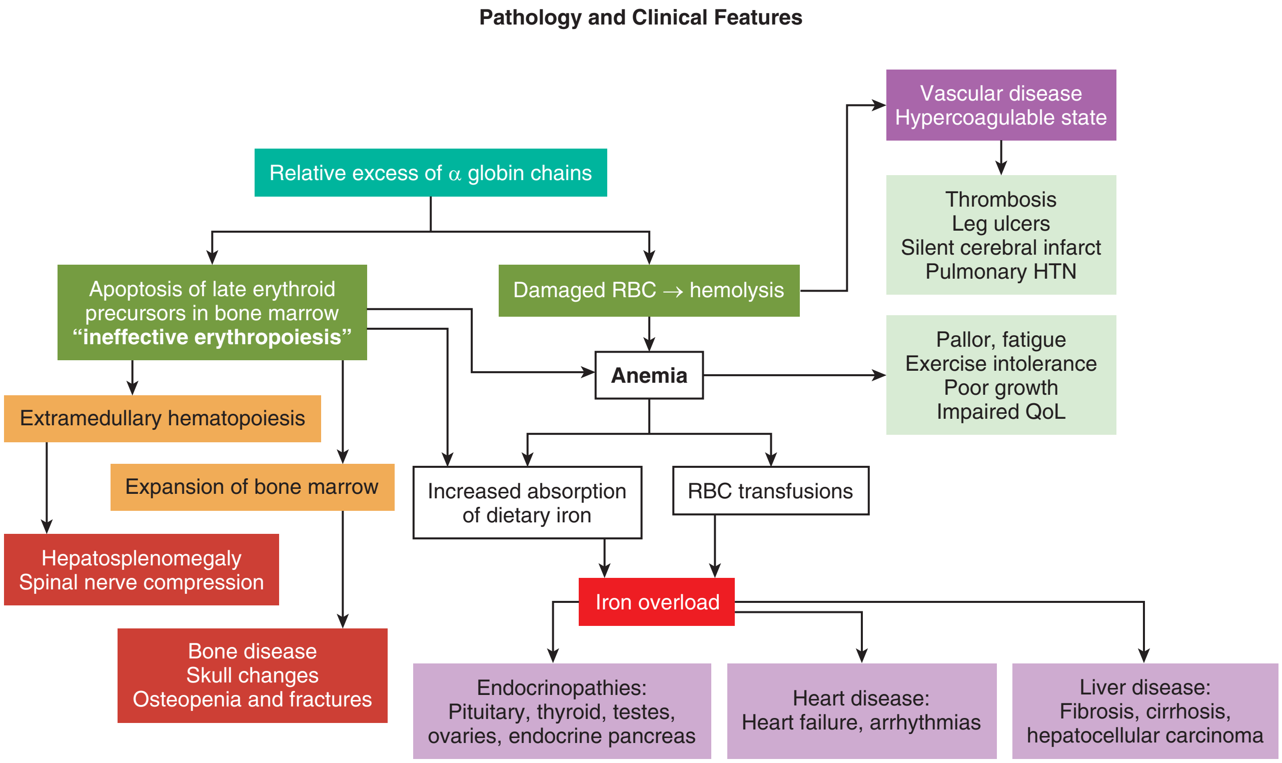
apoptosis and destruction of immature developing erythroblasts in the BM (intramedullary hemolysis).[34–36] Consequently, relatively few of the erythroid precursors undergoing erythroid maturation in the BM survive long enough to be released into the bloodstream as erythrocytes, leading to anemia. Thus, in β-thalassemia, the defect in the erythropoietic pathway is one of impaired differentiation and maturation of the developing erythroid precursors, beginning at the time globin genes begin expression in the proerythroblast-basophilic erythroblast stages. Erythropoiesis is *ineffective*, and the severity of this IE worsens as the imbalance between β- and α-globin synthesis deepens. The occasional erythrocytes that are formed during erythropoiesis bear a burden of inclusion bodies. The reticuloendothelial cells in the spleen, liver, and BM remove these abnormal cells prematurely, which reduces RBC survival as a consequence of this hemolytic anemia.

IE is thus the hallmark of β-thalassemia, triggering a cascade of compensatory mechanisms and resulting in clinical sequelae such as erythroid BM expansion, extramedullary hematopoiesis (EMH), and splenomegaly.[37] The master iron regulatory hormone hepcidin plays an integral and critical role in the pathophysiology of the disease as well (see Chapters 35–37).[38,39] Erythroferrone (ERFE) is a protein which is produced during erythropoiesis, which has the effect of reducing hepcidin production, likely through the BMP/SMAD signaling pathway.[40] During stress erythropoiesis, increased ERFE results in decreased hepcidin which in turn leads to increased iron absorption through the transporter ferroportin at the basolateral side of the intestinal enterocyte, the body mistakenly sensing anemia as being a result of iron deficiency. The greater the erythropoietic activity, the higher ERFE levels rise to, and the greater the suppression of hepcidin. In thalassemia, where IE is a significant feature, ERFE levels are high and therefore hepcidin levels are inappropriately low. Such patients become iron overloaded as a result of increased iron absorption even in the absence of transfusional iron loading. The critical role of hepcidin in iron trafficking is also a factor in iron toxicity in thalassemia. In the absence of IE, hepcidin levels are increased when there is iron overload, thus reducing iron absorption, and also safely sequestering iron in storage sites and preventing deposition in vulnerable tissues. The relatively lower levels of hepcidin driven by ERFE in ineffective erythropoiesis result in iron being able to be more easily redistributed, leading to organ toxicity. When hepcidin production is inappropriately low as a result of increased IE, tissues such as the heart and endocrine organs are exposed to more circulating iron and this results in uptake and organ dysfunction as a result of iron toxicity.

As a result of the anemia, there is increased secretion of EPO, and further proliferation, once again, without maturation. Accumulation of molecules belonging to the transforming growth factor-beta (TGF-β) superfamily of ligands has been described, which inhibits maturation and differentiation. Trapping these ligands has been the focus of a therapeutic intervention to try and improve IE by removing the block on maturation, and promoting more effective erythropoiesis.[41,42] Massive BM expansion does occur, but very few erythrocytes are actually supplied to the circulation. The BM becomes packed with immature erythroid precursors, which die from their burden of precipitated α-globin chains before they reach the reticulocyte stage. Profound anemia persists, driving erythroid hyperplasia to still higher levels. In some cases, erythropoiesis is so exuberant that masses of extramedullary erythropoietic tissue form in the chest, abdomen, or pelvis.

Clinical Manifestations

Anemia and IE are central to the pathophysiology and disease manifestations of thalassemia, and the clinical manifestations are a cascade that results from these (Fig. 41.6). However, there is tremendous heterogeneity in the spectrum of clinical features in the various thalassemia syndromes, determined by the genotype, genetic modifiers, age at presentation, and diagnostic and treatment modalities employed. Two siblings inheriting identical thalassemia mutations sometimes exhibit markedly different degrees of anemia and erythroid hyperplasia. Many factors contribute to this clinical heterogeneity. Individual alleles vary with respect to severity of the biosynthetic lesion. Other modifying factors ameliorate the burden of unpaired α-globin. Levels of γ-globin expression are widely variable in β-thalassemia, with greater production of γ-globin able to reduce the excess of



Pathology and Clinical Features
Relative excess of α globin chains

α-globin. Theoretically, patients may also vary in their ability to solubilize unpaired globin chains by proteolysis. Occasional heterozygous patients have had more severe anemia than expected, possibly because of defects in these proteolytic systems or because of the type of thalassemic mutation. Inheritance of more than the usual complement of α-globin genes may also increase with severity of β-thalassemia because of additional production of unpaired α-globin chains. All of these factors emphasize the essential role of α-globin inclusions in the pathophysiology of β-thalassemia.

In general, in patients who have not been transfused regularly, manifestations are mainly from the effects of IE, with bone changes and vasculopathy dominating, but iron overload remaining an important feature as well. In appropriately transfused individuals, the effects of the now suppressed IE are not prominent, and it is more the effects of iron overload that present as complications.

Beta-Thalassemia Major

Homozygotes or compound heterozygotes with the more severe genotypes are born, usually without prenatal complications, with mild anemia and microcytosis compared with newborns without these mutations. Nevertheless, deficient β-chain synthesis can be demonstrated at birth on the newborn screen, which would show an absence or marked reduction in HbA. As the Hb declines to the physiologic nadir, which is reached sooner as a result of the relative anemia at birth, erythropoiesis resumes under the drive of EPO. However, since the marrow is not able to produce adequate red cells, the Hb level continues to drop leading to further EPO production and BM hyperplasia, and persistent red marrow in bones which would otherwise have converted to yellow marrow. In addition, normally quiescent erythroid precursors in the liver and spleen are activated, with resulting EMH. Clinical manifestations usually emerge as the anemia becomes more pronounced. The diagnosis is almost always evident by 2 years of age.[43] Pallor, irritability, failure to thrive, growth retardation, abdominal swelling caused by enlargement of the liver and spleen, and jaundice are the usual presenting features.[44] Facial and skeletal changes caused by BM expansion develop as the anemia worsens, with frontal and parietal bossing of the skull bones, persistent marrow in the maxilla resulting in underdevelopment of normal sinuses (Fig. 41.7).

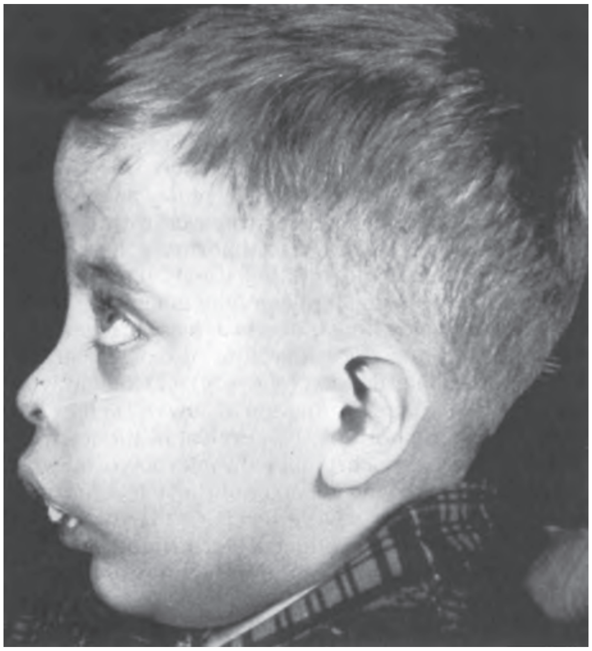

Figure 41.7 THALASSEMIC FACIES. See text for description. *(From Jurkiewicz MJ, Pearson HA, Furlow LT Jr. Reconstruction of the maxilla in thalassemia. Ann N Y Acad Sci. 1969;165:437.)*

Untreated patients die in late infancy or early childhood as a consequence of severe anemia. In a retrospective review from Italy, the average survival of children with untreated thalassemia major was less than 4 years; approximately 80% died in the first 5 years of life.[45] Patients who receive transfusions sporadically may live somewhat longer than untransfused patients, but their quality of life is extremely poor as a result of both the chronic anemia and the IE. The low Hb level and massive organomegaly are usually disabling, and the changes in the facial bones are disfiguring. After 10 to 20 years of weakness, stunted growth, and impaired activity, the undertransfused patients usually succumb to congestive heart failure.

This disastrous symptom constellation, so prevalent in the past, is now rare in most industrialized countries. Nonetheless, the clinical manifestations and complications of untreated or undertreated β-thalassemia major illustrate the principles of the pathophysiology. Furthermore, these descriptions accurately characterize the disease that is still prevalent in many underserved parts of the world.

Beta-Thalassemia Intermedia

Individuals with less severe genotypes have a milder course than that described above, but always have some pathologic features of the disease unlike heterozygotes who are mostly completely asymptomatic. However, this intermediate syndrome has a wide spectrum of severity based on the degree of IE and its consequences, and thus individuals may have mild symptoms to more complex presentations which may move them along the spectrum toward transfusion dependence. Approximately 10% of patients with homozygous β-thalassemia may exhibit a phenotype characterized by intermediate hematologic severity.[2–4,6] The balance of globin chain synthesis is better than in typical thalassemia major because of a less severe defect in β-globin chain synthesis, a decrease in α-globin chain synthesis along with decreased β-globin chain synthesis, or an increase in γ-globin chain synthesis. For example, homozygous β-thalassemia in African Americans, Portuguese, and other populations may be relatively mild, at least for the first two decades of life.[46–48] Homozygotes or mixed heterozygotes for forms of β-thalassemia associated with normal HbA_2 and normal HbF (so called "silent carrier" mutations) also tend to have mild to moderate disease.[49,50]

Unfortunately, many individuals with milder presentations are not appropriately diagnosed, being treated as chronic or refractory iron deficiency instead. More severely affected individuals have more marked IE, bone changes, and more severe anemia, with fatigue, abnormal bones of the skull, hepatosplenomegaly, and pathologic fractures. Individuals may present at a variable age, some in the first decade of life, some in the second, and some as late as the third. Patients do not remain static on the spectrum from thalassemia intermedia to thalassemia major. Complications in these individuals are primarily related to IE, and depending on the severity of the IE, may be mild or more severe. These complications will be described later in this chapter. Those with severe IE and anemia would likely benefit from regular transfusion. However, many such individuals either refuse regular transfusions for fear of transfusion-related infections or iron overload, or are not able to get them for logistic and economic reasons. These individuals may have growth retardation, chronic fatigue and malaise, bone pain, and worsening splenomegaly and still develop iron overload. Splenectomy is often performed when there is a component of hypersplenism contributing to worsening anemia. Gallbladder disease from increased red cell turnover and the development of pigment gallstones is quite common. Progressive EMH may result in paraspinal nodules as described previously. Particularly in splenectomized patients, vascular damage from fragmented and abnormal red cells, complicated by thrombocytosis may lead to clinical manifestations including the development of chronic, non-healing leg ulcers from poor perfusion and the effects of arterial endothelial damage and a possible hypercoagulable state leading to cerebral infarcts and development of pulmonary hypertension. Some individuals may remain in the intermedia spectrum until adulthood, receiving very few transfusions for stress situations such as severe infections or surgery, when they may have a drop in Hb and worsening symptoms related to anemia.

Clinically significant iron loading as a result of increased absorption is seen even in patients with infrequent transfusions (see Chapters 35 and 36). Iron overload may result in diabetes and endocrine disturbances, typically by fourth decade of life, though cardiac deposition is relatively rare in true thalassemia intermedia individuals.

Individuals with the most severe form of the disease will usually be placed on a regimen of regular transfusions. In appropriately transfused individuals who have suppressed IE, complications are now mostly related to those resulting from transfusional iron overload.

Beta-Thalassemia Minor

Heterozygotes for β-thalassemia are usually asymptomatic. Often the diagnosis is made as a result of their family history, a prenatal screen, as part of the workup for refractory iron deficiency anemia, or by the chance finding of the characteristic hematologic changes during a routine study. In general, thalassemia trait carries no direct clinical symptoms or pathologic consequences for the patient. Usually, they have adapted to a mild microcytic anemia, with no symptoms, no overt evidence of IE or EMH. A controlled study reported that individuals with the β-thalassemia trait suffer from fatigue and other symptoms indistinguishable from those with mild anemias from other causes. There was no difference in the frequency of palpable splenomegaly between the thalassemic and control groups.[51] There are some reports in the literature of individuals who have symptoms from anemia and may even have mild splenomegaly, but in the absence of genetic testing, it is not clear that these were all heterozygotes only. In situations in which there is an adaptive increase in Hb, such as endurance activities like running marathons, or living at high altitude, individuals may have some difficulty. The diagnosis of thalassemia trait assumes particular importance in women who are pregnant or considering pregnancy because of the potential for having a child with thalassemia major. During pregnancy, the anemia of thalassemia trait often becomes more severe, but transfusions are rarely necessary. Increased folic acid supplementation may improve Hb during this period. Because iron deficiency may occur during pregnancy, iron supplementation has been advised to avoid compounding the causes of anemia.[52,53] Studies have suggested there may be an increased tendency for gallstones and cholecystitis, but otherwise this condition should be largely asymptomatic.[54] Some β-thalassemia carriers have increased iron stores, although this is most often a result of inappropriate long-term iron therapy based on a misdiagnosis. In countries where there is a relatively high frequency of genetic determinants for hemochromatosis, the possibility of their coinheritance should be borne in mind if a patient with β-thalassemia trait with an unusually high plasma iron or serum ferritin level is encountered. Iron supplementation is only necessary if there is true iron deficiency, and routine supplementation to raise the Hb level is futile and should not be done. These individuals should seek genetic counseling when ready for childbearing.

Laboratory Findings

In order to make the diagnosis, the clinician must consider the ethnicity, family history, clinical presentation, physical exam as well as laboratory parameters. The laboratory diagnosis of the thalassemia syndromes has traditionally been based on careful interpretation of the complete blood count, including the red cell indices, the review of the peripheral blood smear, and characterization of the type of Hb produced. Hb levels vary based on the severity of the underlying genotype, but the anemia is always microcytic with low red cell indices. The smear shows variable hypochromia and the presence of abnormal shapes and sizes of cells, all more so in individuals with increasing severity of anemia. There is a reduction or absence of production of HbA, and thus an increase in HbF and HbA2 on Hb fractionation. Special staining, α-, β-, and γ-globin assessments are performed in some sophisticated laboratories, along with some degree of genotyping, especially for known mutations. In the developed world, it is now possible to characterize the disease more completely, including all of the possible genetic modifiers with the easy availability of sophisticated DNA testing, including whole exome or genome sequencing. While this is not routinely done for all patients, especially those with mild clinical manifestations, in more complex cases, it may be used to fully explain the clinical picture. There may also be some predictive value in genotyping for some of the newer therapies, as will be described later. Family members should also have testing if they have not been tested previously.

The diagnosis is usually fairly easy to make, though the following may be considered if it is not immediately clear:

- congenital sideroblastic anemia, one of the rarer instances when a BM exam or specific genetic testing may be needed to make the diagnosis
- juvenile chronic myelogenous leukemia may be superficially considered, because of the elevated HbF levels, but other testing is quite straightforward to make this diagnosis

Homozygous β^0 Thalassemia

Infants are born with relative anemia and microcytosis. The Hb level decreases progressively during the first months of life. When the child becomes symptomatic, the Hb level may be as low as 3 to 4 g/dL. RBC morphology is strikingly abnormal, with many microcytes, bizarre poikilocytes, teardrop cells, and target cells (Fig. 41.8). A characteristic finding is the presence of extraordinarily hypochromic, often wrinkled and folded cells (leptocytes) containing irregular inclusion bodies of precipitated α-globin chains. Nucleated RBCs are frequently present in peripheral circulation. The reticulocyte count is 2% to 8%, lower than would be expected in view of the extreme erythroid hyperplasia and hemolysis. The low count reflects the severity of intramedullary erythroblast destruction. The white blood cell count is elevated. A moderate polymorphonuclear leukocytosis and normal platelet count are typical unless hypersplenism has developed. The BM (not necessary for diagnosis) exhibits marked hypercellularity caused by erythroid hyperplasia. The RBC precursors show a maturational arrest with defective hemoglobinization and reduced amounts of cytoplasm.

The osmotic fragility is strikingly abnormal. The RBCs are so markedly resistant to hemolysis in hypotonic sodium chloride solution that some are not entirely hemolyzed even in distilled water. Even before transfusion therapy is initiated, the serum iron and

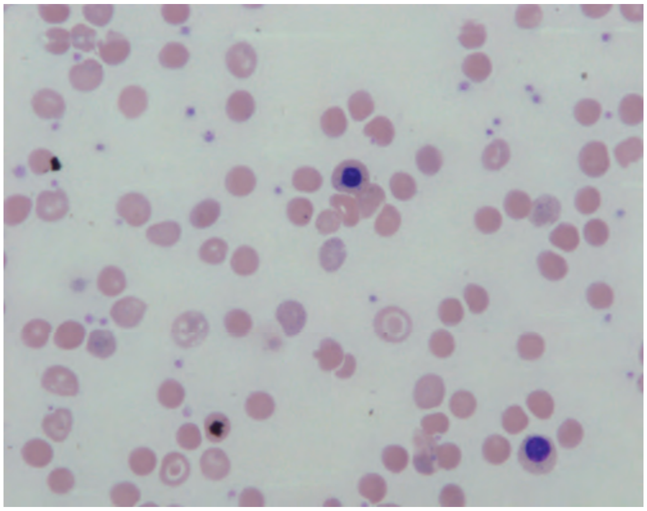

Figure 41.8 MORPHOLOGIC APPEARANCE OF THE PERIPHERAL BLOOD FILM IN A CASE OF SEVERE β-THALASSEMIA. Note the bizarre cells, the hypochromia, nucleated red blood cells, target cells, and polychromasia.

transferrin saturation and serum ferritin may already be increased as a result of increased iron absorption,[55] thus ruling out iron deficiency as an alternate diagnosis.

The Hb profile reveals predominantly HbF. In patients with homozygous β^0-thalassemia, HbA is absent throughout life, unless transfused. In β^+-thalassemia HbA may be very low or undetectable in the newborn but present in reduced amounts in later life. The levels of HbA2 in thalassemia major are variable, probably because of increased numbers of F cells that have a decreased HbA2 content.[2] Other biochemical abnormalities of the RBC in cases of thalassemia major include a postnatal persistence of the RBC in antigen and a decrease of RBC carbonic anhydrase; these findings are probably also caused by the elevated levels of circulating F cells.

The intraerythrocytic inclusions in the peripheral blood cells of patients with thalassemia, termed Fessas bodies,[56] are especially prominent after splenectomy. These inclusions, best seen by staining with supravital staining (Brilliant Cresyl Blue) or by phase microscopy, are aggregates of precipitated, denatured α-chains.[57] They are also found in large numbers within erythroid precursors in the BM.

RBC survival in cases of thalassemia major is variable but usually markedly decreased. The ^{53}Cr half-life ranges between 6.5 and 19.5 days compared with the normal half-life of 25 to 35 days,[35] but there is some variability with cells containing more fetal Hb surviving longer. Increased plasma iron turnover and poor use of radiolabeled iron provide further evidence of IE.[35]

Unconjugated bilirubin levels are elevated, in the range of 2.0 to 4.0 mg/dL at the time of diagnosis but may rise substantially as the anemia worsens in the absence of transfusion. Serum aspartate aminotransferase levels are frequently increased at diagnosis because of hemolysis. Alanine aminotransferase levels are usually normal before transfusion therapy but may rise subsequently because of iron-induced hepatic damage or viral hepatitis. Lactate dehydrogenase levels are markedly elevated as a consequence of IE. Haptoglobin and hemopexin are reduced or absent.[58]

Hypersplenic patients may have low white cell and platelet counts, and after splenectomy, leukocytosis and thrombocytosis are common. Asplenic individuals usually have large, flat "pseudo-macrocytes," or leptocytes that appear larger in two dimensions because they are so devoid of Hb that they collapse flat on the slide like a deflated balloon, and small, deformed microcytes, as well as markedly increased nucleated red cell counts, and the white cell count frequently has to be corrected for their presence. Staining of the blood with methyl violet, particularly in splenectomized subjects, reveals stippling or ragged inclusion bodies in the red cells.

When transfusions are initiated, the Hb level rises to the mild to moderate anemia range, being higher in patients on regular transfusions and generally lower in those receiving on-demand transfusions. The mean corpuscular volume (MCV) and Hb fractionation reflects transfused blood as well. Iron parameters are altered to reflect iron overload as transfusions continue. Serum iron and transferrin saturation, as well as ferritin levels are elevated, and remain so, with the ferritin level declining in response to chelation therapy.

Transfusion complications include the development of auto- or alloantibodies with a positive DAT and antibody screen, iron-related organ dysfunction, hepatic, and endocrine. All of these parameters must be regularly monitored in transfusion-dependent patients.

Homozygous or Compound Heterozygous β^+ Thalassemia

In these individuals, the Hb levels are generally higher, but otherwise the hematologic changes are similar. The more severe the anemia, with greater IE, the more the peripheral smear resembles that of a thalassemia major patient prior to starting transfusions, as noted above. Examination of the BM, if performed, would confirm IE to a variable degree, with more severe patients having the picture of untreated thalassemia major. Hb fractionation shows a variable amount of HbA depending on the specific genotype, and the rest is HbF and A2, or in cases of HbE-thalassemia, a proportion of HbE. Even in the absence of transfusions, iron studies will show a steady rise in serum iron, transferrin saturation, and ferritin as a result of increased intestinal absorption, the rate of rise determined by the degree of IE. With intermittent or regular transfusions, the iron levels will rise more rapidly, and follow the same course as individuals with thalassemia major.

Heterozygous β-Thalassemia

Inheritance of a single β-thalassemia allele usually results in a mild anemia. The classic picture of β-thalassemia minor is a mild microcytic anemia (Hb averages 1 or 2 g/dL lower than that seen in normal persons of the same age and gender, typically 9 to 11 g/dL, MCV 50 to 70 fL). The red cell count is usually normal or elevated. HbF levels decline more slowly than usual in the first year of life, and the diagnostic elevated HbA2 levels are established by approximately 6 months of age.[59–61] Strong intrafamilial correlations of both HbA2 and MCV are noted.[62,63] The HbA2 level is increased to 3.5% to 7%. The level of fetal Hb is elevated in approximately 50% of cases, usually to 1% to 3% and rarely to greater than 5%. The RBC count is increased or normal. The RBCs are characteristically hypochromic (mean corpuscular hemoglobin [MCH] <26 pg). Osmotic fragility is decreased; indeed, a one-tube osmotic fragility test has been used in the past for mass screening.[60] The smear shows varying numbers of target cells, poikilocytes, ovalocytes, and basophilic stippling (Fig. 41.9). The reticulocyte count is normal or slightly elevated. RBC survival is normal, iron utilization is decreased, and slight IE is present.[61] Iron studies are normal, unless concomitant iron deficiency is also present, in which case the transferrin saturation and ferritin are low. In this situation, the Hb is lower, as are the red cell indices, and

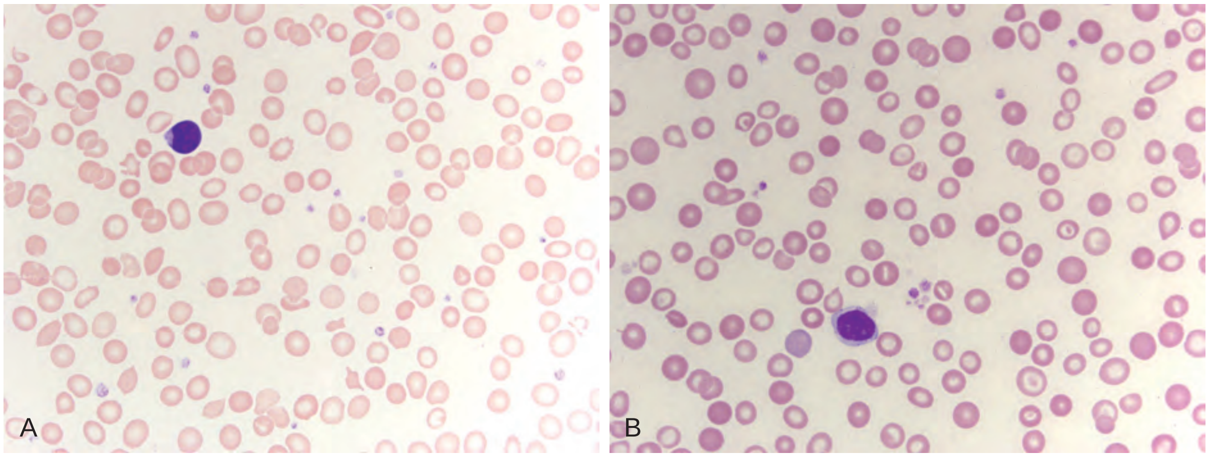

Figure 41.9 MORPHOLOGY OF THE PERIPHERAL BLOOD FILM IN A PATIENT WITH HETEROZYGOUS β-THALASSEMIA (A) AND A PATIENT WITH HETEROZYGOUS α-THALASSEMIA (B). Note the profound hypochromia and microcytosis and the many target cells. *(From Pearson HA, Benz EJ Jr. Thalassemia syndromes. In: Miller DR, Baehner RL, McMillan CW, eds. Smith's Blood Diseases of Infancy and Childhood. 5th ed. St. Louis: CV Mosby; 1984:439.)*

the red cell count. The BM (not usually done) in heterozygous β-thalassemia shows slight erythroid hyperplasia with rare red cell inclusions. Megaloblastic transformation as a result of folic acid deficiency occurs occasionally, particularly during pregnancy. A mild degree of IE is noted, but red cell survival is normal or nearly normal.

β-Thalassemia With Normal A2 Level

Rare forms of β-thalassemia are seen in which heterozygotes have a completely normal hemogram, or with mild microcytic anemia but with a completely normal Hb pattern on electrophoresis or high-pressure liquid chromatography (HPLC). This can be confused with the more common heterozygous α-thalassemia and may cause difficulties in genetic counseling and prenatal diagnosis. Based on hematologic studies, two main classes of "normal HbA2 β-thalassemia"—sometimes called types 1 and 2—are seen.[64]

Type 1, the "silent" form of β-thalassemia,[2] is characterized in heterozygotes by a normal hemogram—there is no anemia, and the MCV is normal. Although this condition can be partly identified by demonstrating a mild degree of globin-chain imbalance, with α-to-β synthesis ratios of approximately 1.5:1, it can only be diagnosed with certainty by DNA analysis. Compound heterozygotes for this condition and β^0-thalassemia have a mild form of β-thalassemia intermedia.

Normal HbA2 β-thalassemia type 2 in heterozygotes has a hematologic profile of mild microcytic anemia which is indistinguishable from typical β-thalassemia with elevated HbA2 levels.[64] The homozygous state has not been described. The compound heterozygous state for this gene and for β-thalassemia with raised HbA2 levels is characterized by a clinical picture of severe transfusion-dependent β-thalassemia.

Dominant β-Thalassemia

The clinical features of the dominant β-thalassemias resemble the features of thalassemia intermedia.[2] The blood picture shows the usual thalassemia changes, and there is moderate anemia and splenomegaly. The marrow shows erythroid hyperplasia with well-marked inclusion bodies in the red cell precursors, which may be seen in the peripheral blood after splenectomy. Hb analysis shows HbA and elevated HbA2, but the HbF level is not usually elevated much higher than that seen in β-thalassemia heterozygotes.

Other Laboratory Findings

Serum zinc levels may fall to abnormally low levels. A relationship between this finding and growth failure has been postulated but not established.[65,66] Low levels of plasma and leukocyte ascorbic acid are common in thalassemic patients because of increased metabolism of the vitamin to oxalic acid in the presence of iron overload.[67,68] Biochemical evidence of folic acid deficiency may occur as a result of excessive consumption secondary to increased requirements.[69,70] The serum levels of α-tocopherol are often reduced to less than 0.5 mg/dL, and increased RBC membrane lipid peroxidation has been described.[71–73]

Coagulation abnormalities consistent with liver disease (i.e., lowered levels of factors II, V, VII, IX, and X) may occur in older patients with hepatitis or iron-induced hepatic injury.[74] Only rarely are the abnormalities sufficient to require specific therapy. However, the combination of mild thrombocytopenia from hypersplenism and low coagulation factors and platelet dysfunction from liver disease may cause or aggravate bleeding.[75]

Numerous laboratory abnormalities reflect the accumulation of excessive iron and the consequences of iron-induced organ damage, and they are described in the following sections.

Treatment

The overall goals of management of the thalassemia syndromes are:

- To optimize the level of Hb, so as to facilitate growth and development in children, and overall activity levels in all, with or without transfusion.
- To minimize the complications of IE, by suppressing erythropoiesis, or facilitating erythroid maturation, particularly in those who are not regularly transfused.
- To prevent complications related to iron overload, especially in regularly transfused individuals.
- To provide a near-normal life expectancy with an optimized quality of life.

Transfusion and chelation therapy, described subsequently in detail, have ameliorated many of the most striking manifestations of the disease. Bone marrow transplantation (BMT) has allowed for the cure in some patients. Gene therapy and drugs mitigating the process by which ineffective erythropoiesis is aggravated by cytokines are emerging modalities. Current clinical management and associated clinical manifestations and complications have been reviewed in a number of publications.[2,76–81]

Transfusion Therapy

Transfusion therapy for thalassemia was once administered as a palliative measure only when patients became symptomatic. These periodic transfusion regimens were unsatisfactory even for those limited purposes; they did very little to address the underlying IE, and thus did not prevent complications such as bone disease, vascular disease, and overall quality of life. Consequently, several centers initiated transfusion programs in which patients received regular transfusions to keep their Hb levels high enough to ameliorate these symptoms,[82,83] but the median survival time of patients transfused to maintain Hb levels of 7 to 8 g/dL in the United States in the 1960s was only 17 years of age.[83,84] "Hypertransfusion" programs were designed initially to maintain Hb levels above 8 g/dL, but in their more modern application, which is in current use, Hb levels are usually maintained above 9.5 to 10.5 g/dL. From the model of physiologic anemia in the newborn, it appears that the renal threshold for increased EPO secretion is in that range. To suppress this EPO drive of mostly IE, maintaining the Hb above that range would adequately suppress IE, thus minimizing complications related to it. This is different than other congenital anemias such as Diamond-Blackfan anemia (DBA), where lower thresholds have been used since IE is not a component of the disease. This range is quite close to the Hb levels of heterozygous individuals who are quite asymptomatic, and is thus able to maintain normal growth and development, and a level of activity that optimizes quality of life. A review of transfusion guidelines may be found at https://www.thalassemia.org/thalassemia-management-checklists-now-available-download/, and https://thalassaemia.org.cy/publications/tif-publications/.

A more vigorous transfusion program (supertransfusion) aimed at keeping Hb levels above 12.0 g/dL is no longer recommended.[85] This approach rested on the assumption that the benefits of further suppression of erythropoiesis and gastrointestinal iron absorption will offset the increased need for RBCs. However, several studies have demonstrated that transfusion requirements (and therefore the rates of transfusional iron loading) increase as the Hb level is raised in both splenectomized and nonsplenectomized patients (Fig. 41.10).[86–88] As a result, the consistent maintenance of Hb levels above 11 or 12 g/dL results in excessive iron accumulation without proportional clinical benefit, and supertransfusion protocols should be reserved for patients with poor tolerance of lower Hb levels because of cardiac disease or other reasons.

Alternative approaches to conventional transfusion therapy have been proposed to reduce the rate of transfusion iron loading. These approaches have generally relied on the concept that younger RBCs (neocytes) will circulate longer in the recipient than older RBCs. Preclinical experiments based on the difference in density between younger and older RBCs established the validity of this approach.[89,90] However, in prospective clinical trials, blood requirements were reduced only by 13% to 20%.[91–93] This reduction in iron loading did not outweigh the disadvantages of neocyte transfusions that included increased cost, wastage of 50% of the donor RBCs, and increased

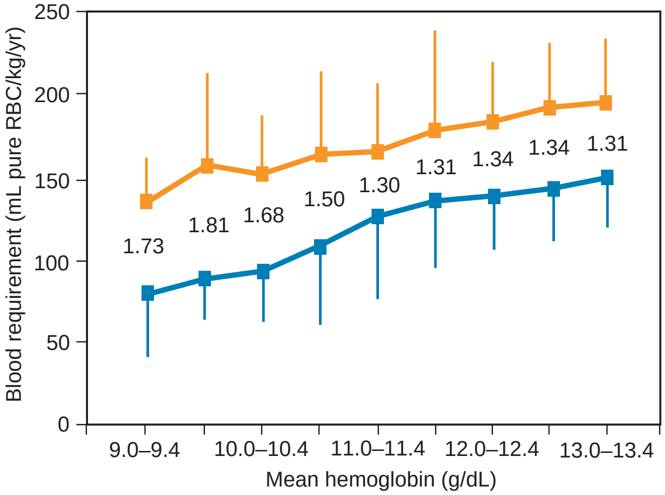

Figure 41.10 RELATIONSHIP BETWEEN TRANSFUSION REQUIREMENTS AND MEAN HEMOGLOBIN LEVEL MAINTAINED BY PATIENTS WITH THALASSEMIA MAJOR. *Blue*, Splenectomized patients, *yellow*, nonsplenectomized patients. *RBC*, Red blood cell. *(Adapted from Rebulla P, Modell B. Transfusion requirements and effects in patients with thalassemia major. Lancet. 1991;337:277.)*

TABLE 41.2 **Indications to Initiate Regular Transfusion Therapy in Nontransfusion-Dependent Thalassemia**

Declining hemoglobin with enlargement of the spleen
Growth failure
Poor school performance
Pregnancy
Surgery
Decreased exercise tolerance
Failure of secondary sexual development
Bony changes

Poor quality of life
Primary prevention and management of the following: 1. thrombotic or cerebrovascular disease 2. pulmonary hypertension/heart failure 3. extramedullary hematopoiesis 4. leg ulcers

donor exposures. The use of automated exchange transfusion has been proposed as another approach to reducing iron loading in patients with thalassemia.[94] With this method, RBCs are removed from the patient at the same time that new donor RBCs are transfused. This approach has been applied successfully to transfusion therapy for sickle cell disease. However, the goal of transfusion therapy in sickle cell disease is the replacement of HbS-containing RBCs with HbA-containing RBCs irrespective of the total Hb level. In contrast, the goal of transfusion therapy in patients with thalassemia is to maintain a specific total Hb level. Despite these different goals, studies of automated exchange transfusion in patients with thalassemia have demonstrated a reduction in net RBC requirements of 30% to 50%, either by reducing the amount of blood administered at the usual transfusion interval or by prolonging the interval between transfusions.[94,95] The benefits of this approach are probably attributable to the removal of previously transfused RBCs from the patients and replacement with younger, recently donated RBCs, reducing the overall age of the circulating RBC population.

The decision to initiate transfusion therapy should take into account the overall clinical condition of the patient as well as the Hb level. Patients with severe and persistent anemia (Hb <6 to 7 g/dL) usually also have failure to thrive, decreased activity level, and irritability. For these patients, transfusion therapy should begin after confirmation of the diagnosis of thalassemia and after demonstration that acute factors such as a febrile illness or folic acid deficiency are not confounding the assessment of the severity of anemia. For patients with higher Hb levels, the decision to begin transfusion depends on the careful assessment of the child's clinical findings. For example, some children with thalassemia have early and pronounced facial bone deformities caused by BM expansion despite a Hb level of 8 g/dL or higher. For such children, the benefits of transfusion therapy may outweigh the risks. In contrast, some patients with thalassemia have little or no clinical difficulty despite a persistent Hb level of 7 to 8 g/dL, and the benefits of transfusion therapy may be small. Determination of genotype may provide some guidance by distinguishing patients with more severe defects in β-globin production from those with less severe defects, but the overlap between genotype and phenotype in thalassemia still requires reliance on clinical assessment.

The ability to maintain a Hb level compatible with comfortable survival in the absence of regular transfusions is the generally accepted criterion for the diagnosis of thalassemia intermedia. In other words, distinguishing between thalassemia major and thalassemia intermedia, which in turn is the distinction between initiating a regular transfusion program or not, requires consideration of the Hb level and the quality of life (Table 41.2). These two parameters do not have a predictable relationship. Patients with thalassemia and Hb levels of 7 g/dL may be relatively symptom free, but patients with Hb levels of 9 g/dL may have numerous problems related to IE. Thus, the assessment of the patient rather than the Hb level alone is essential in deciding who does not require regular transfusions and therefore, by definition, has thalassemia intermedia. Some nontransfused patients have normal growth and sexual development, few medical problems, and normal or near-normal survival rates. However, others develop disfiguring facial changes, markedly delayed growth and sexual maturation, heart failure, severe osteoporosis, repeated fractures, arthritis, and massive splenomegaly. Calling the condition of this latter group "thalassemia intermedia" implies a milder disease than thalassemia major but, in fact, the patients' quality of life does not compare favorably with the quality of life of patients with thalassemia major. However, many such individuals either refuse regular transfusions for fear of transfusion related infections or iron overload, or are not able to get them for logistic and economic reasons. If the decision is made to manage the patient initially without regular transfusions, periodic reassessments of the patient's clinical condition, including appearance, growth, and development, and bone expansion are crucial.[96] Short-term transfusion therapy may be useful during pregnancy or in the management of cardiac and other serious complications. The need for regular transfusions often develops in adults with thalassemia intermedia because of a further decline in the Hb level or a growing intolerance of the anemia.[97]

In the most severe forms of the disease, transfusions are generally begun in the first or second year of life, and continued monthly. In order to minimize the risk of alloimmunization, it is recommended to have a limited extended phenotype of the recipient red cells, generally including the C, D, E, and Kell red cell antigens, but the standard may vary by region, and only involve the standard ABO and Rh antigens in areas where the donor and recipient pools are ethnically similar. There is no evidence that irradiation of the red cells is of specific benefit to patients with thalassemia. With the use of current additive solutions, the duration of storage of donor RBCs has only a small effect on the 24-hour recovery and the survival of the RBCs in each transfused unit. However, for patients with thalassemia major who undergo transfusion every 2 to 5 weeks, these small differences may have a significant impact on the annual consumption of blood. Consequently, the use of donor RBCs that have been stored for less than 7 to 10 days strikes a reasonable balance between the potential reduction in transfusion iron loading and the efficient use of the blood bank inventory. The use of volunteer blood donors remains the standard for patients with thalassemia. Although some families of children with thalassemia prefer directed donations, this approach has not reduced the rate of transfusion-transmitted infections among blood recipients in general and has not been shown to reduce the rate of alloimmunization in thalassemia. If directed donations are used, close relatives should be avoided because stem cell transplantation may be a later therapeutic option. Washed, filtered, or frozen red cells where the majority of the white cells and plasma-protein components are removed, are recommended only for individuals with severe or recurrent allergic transfusion reactions. The volume of packed red blood cells (PRBCs) transfused at each monthly visit is generally 15 mL/kg in children, to increase to a full unit when the child is about 15 kg in weight. Split units are not recommended since they do not afford the benefit of the full amount, and yet expose the recipient to another donor. Instead, the interval between transfusions may be shortened instead to 3 weeks or even 2 weeks, until the child reaches about 36 to 40 kg, when a second unit may be added to each transfusion visit. Most adults receive 2 units of PRBCs every 2 to 4 weeks. Occasionally, for logistical reasons, more blood may be administered at longer intervals, but this is not recommended because BM erythropoietic activity may be affected with wide variations in Hb levels (see box on Guidelines for Transfusion Therapy).

The clinical benefits of hypertransfusion programs are dramatic. The growth of younger children follows normal percentiles for height and weight.[98] Erythropoiesis is significantly suppressed as evidenced by decreased numbers of reticulocytes and normoblasts and TfR1 levels.[99,100] Hypertransfusion reduces or prevents the enlargement of the liver and spleen. Abnormal facies and bone fractures occur less frequently. The overall sense of well-being allows normal age-appropriate activities.[101,102]

There are many adverse effects of regular transfusions. Transfusion reactions may occur, ranging from non-hemolytic complications like febrile reactions, allergic reactions including urticarial reactions and rare anaphylaxis, to hemolytic complications like acute and delayed hemolysis. The development of autoantibodies and alloantibodies is well known in thalassemia patients. Alloantibodies make it harder to crossmatch blood for patients, though the incidence of development of new alloantibodies is declining with the institution of more standard extended typing.[103] Autoantibodies may also increase transfusion requirements, and should be appropriately treated when clinically significant. Other, longer-term complications of transfusions include transfusion-associated infections, the rates of which have gone down tremendously in the developed world, and iron overload, requiring chelation therapy.

GUIDELINES FOR TRANSFUSION THERAPY

Although some of the details of a transfusion program for patients with thalassemia major vary from center to center, the following guidelines are important for achieving the benefits while controlling the risks of a transfusion program. The rationales for these guidelines are discussed in the text.

1. Obtain a complete or limited extended (C, D, E, Kell) RBC antigen profile before the first transfusion. For patients who come to a new center after receiving transfusions elsewhere, contact the previous blood bank for information about alloantibodies and transfusion reactions.
2. Goal: maintain the pretransfusion hemoglobin level above 9.5–10.5 g/dL.
3. Administer 10–15 mL/kg of packed red blood cells (PRBCs) in children (in whole unit increments, avoid split units), 1–3 units PRBCs in adults at each visit.
4. Transfuse every 2–4 weeks.
5. Use leukoreduced packed RBCs that have been stored for less than 10–14 days.
6. Irradiation of units is not required.
7. Consider washed units only for individuals with frequent/severe allergic reactions.

Iron Toxicity

Transfusional iron overload or secondary hemochromatosis is the most consequential long-term complication that all patients receiving regular transfusions develop.[78] Irrespective of age at which transfusions are initiated, iron overload develops after about 15 transfusions because of the body's inability to physiologically excrete excess iron. If not treated, iron overload eventually results in deposition in the organs, particularly the heart and endocrine organs resulting in significant morbidity and even mortality from cardiac complications of myocardial siderosis.[76] Iron overload is discussed elsewhere, in Chapter 37, but in this section, the discussion will be focused specifically on the nuances related to thalassemia.[104]

Each unit of packed RBCs contains approximately 200 to 250 mg of iron. Based on usual blood requirements in patients with thalassemia major, the rate of transfusional iron accumulation is approximately 0.30 to 0.60 mg/kg/day (Fig. 41.11). The massive IE associated with the intermedia and major thalassemias leads to excessive gastrointestinal iron absorption that adds to the transfusional iron burden, although absorption is reduced when a Hb level above 9 g/dL is maintained.[105,106] Iron causes toxicity to cells as a result of the generation of free radicals via the Fenton reaction. These radicals cause oxidative damage to cellular components (including lipids and protein) and intracellular organelles (Fig. 41.12). Iron toxicity to tissues is a function of tissue iron burden, tissue iron sensitivity, and duration of exposure (see Fig. 41.11).

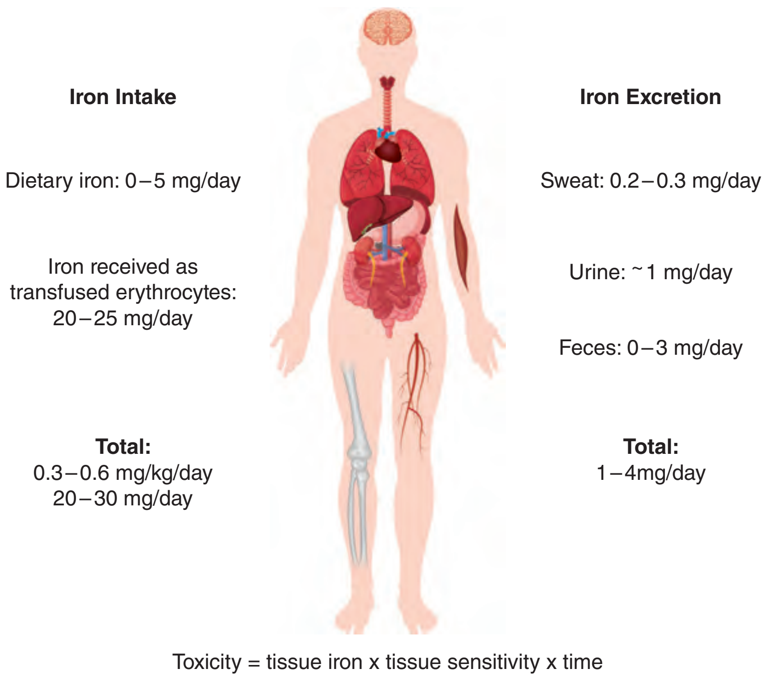
Phlebotomy, the most efficient method of removing iron in other situations, is precluded in severely anemic patients with thalassemia owing to transfusion dependence.

In general, maintaining normal ascorbic acid levels optimizes iron excretion because it increases tissue iron turnover in the plasma. A relationship between iron overload and ascorbic acid depletion, first suggested by the epidemiology of scurvy among the Bantu, exists in thalassemia major.[67,107] For thalassemia patients with low levels of ascorbic acid, daily supplementation with 100 to 200 mg of this vitamin increases urinary iron excretion in response to deferoxamine by approximately twofold.[68,108] Ascorbic acid may retard the conversion of ferritin to hemosiderin and therefore allow more iron to remain in the chelatable form.[109,110] However, it can also enhance iron-mediated peroxidation of membrane lipids[111,112] as well as membrane damage in cultured myocardial cells.[113] Cardiac toxicity manifested as arrhythmias and decreased ventricular contractility has been attributed to vitamin C therapy.[114] *Thus, ascorbic acid should only be used under continuous chelator coverage, and only in patients who are ascorbate depleted.*

Assessment of Iron Stores

Iron acquired by transfusions bypasses the body's normal gatekeeper of iron influx, the gastrointestinal tract, through which iron absorption is exquisitely regulated by hepcidin. This excess transfusional iron cannot be actively excreted, and it is taken up by normal storage organs, the liver and the macrophages of the reticuloendothelial system (RES). When the capacity for storage in these organs is overwhelmed, iron spills over into parenchymal tissue, generating free radical damage with cellular membrane lipid peroxidation and leading to end-organ dysfunction, particularly affecting the liver, endocrine system, and myocardium.

Iron stores were once almost exclusively assessed by measuring serum ferritin levels, with liver biopsy and quantitative iron measurement being used only in more advanced centers. The latter is a painful and invasive test, with a significant risk of complications, and thus not attractive to patients. Magnetic resonance techniques have been developed in the past two decades which allow more accurate assessment of tissue iron and allow the treatment regimen to be tailored. Magnetic resonance imaging (MRI) with proton transverse relaxation rates (R2) with spin-echo imaging, signal intensity ratios, and gradient-echo T2* are currently the preferred method to assess LIC.[115–119] Direct comparisons with hepatic tissue samples demonstrate significant correlations ($r = 0.97$) with biopsy-measured LICs.[116,118–122]



Iron Intake
Dietary iron: 0–5 mg/day
Iron received as transfused erythrocytes: 20–25 mg/day
Total:
0.3–0.6 mg/kg/day
20–30 mg/day
Iron Excretion
Sweat: 0.2–0.3 mg/day
Urine: ~1 mg/day
Feces: 0–3 mg/day
Total:
1–4mg/day
Toxicity = tissue iron x tissue sensitivity x time

Figure 41.11 Iron overload in thalassemia is an imbalance between iron loading from transfused red cells and increased absorption, and the innate inability to excrete excess iron.

Strong evidence supports that with proper calibration, the measurement and mapping of liver iron concentrations (LIC) using MRI is an extremely effective approach for the regular assessment of the effectiveness of chelation therapy.[123] Myocardial T2* MRI has been able to quantify iron loading in the heart as well. However, it is now clear that there is a variable correlation between hepatic and cardiac iron concentrations.[124] Based on these assessments, it is now possible to track iron levels in two tissues to tailor chelation therapy, the LIC, which is normally less than 1.5 mg/g dry weight, and the myocardial iron level measures as a T2* value, normally more than 20 ms. LIC values between 3 and 7 mg Fe/g dry weight appear to be associated with minimal toxicity, while LIC levels greater than 15 mg Fe/g dry weight are associated with a greater risk of iron-induced heart disease.[125] Experience with cardiac MRI suggests that changes in T2* reflect levels of iron in the heart and may predict adverse changes in cardiac function. Cardiac T2* values are predictive of arrhythmias and cardiac failure over 1 year.[126] Cardiac MRI T2*-directed treatment results in improved chelation and iron stores.[127] MRI assessment of iron overload cannot be used in patients with pacemakers or those who are claustrophobic. Future MRI use may involve the quantification of iron concentration of endocrine glands to predict or monitor dysfunction.[128–130]

Measurements of LIC by magnetic susceptometry using a superconducting quantum interference device (SQUID) also correlate well with biochemical measurements of tissue iron.[131,132] At present, measurement of tissue iron by SQUID is limited to the liver, and the instruments are available in only a few sites in the United States of America and Europe. Importantly, the SQUID is not an enclosed space, so claustrophobia is not an issue.

Serum ferritin levels are safe, inexpensive, and readily available, and serial measurements may be predictive both of critical complications such as iron-induced heart disease and of adverse effects of chelation therapy such as impairment of vision and hearing. However, single ferritin levels may correlate poorly with LIC because it is an acute-phase reactant and may be influenced by inflammation, vitamin C deficiency, hepatitis, and other infectious states. Multiple studies correlating serum ferritin levels with liver iron measurements by both biopsy and MRI have shown a significant correlation, but there is marked variability between patients, confirming the low reliability of this measurement as a measure of total body iron. Transferrin saturation is not very useful in evaluating the severity of iron overload in patients with thalassemia because the massive IE usually results in a transferrin saturation greater than 60% even in the absence of iron overload.[133]

Previous standard practice was to initiate chelation in thalassemia patients when the serum ferritin reached 1000 mcg/dL. However, given the unreliable nature of this parameter, and since we can quantify the rate of iron loading, knowing the volume of blood transfused, and its iron content, this is not a reasonable starting point anymore. Chelation should be initiated after the patient has received about 15 transfusions (by which time the liver iron would be estimated to be approximately 6 to 8 mg/g DW.) A baseline MRI of the liver should be performed to quantify iron and provide a starting point for monitoring efficacy. Liver MRIs are recommended annually. In children who are chelated, other organs tend not to load iron since it is well sequestered in the liver and RES. For this reason and because it requires a fairly long breath-hold, cardiac imaging is usually not performed till after 10 years of age.[134] Adults with a longer-standing disease should have cardiac iron assessments along with liver iron assessments. Ferritin levels may still be of use to follow trends, and guide the use of interval MRI assessments or changes in chelation regimens. Ferritin levels are still used almost exclusively where MRI is not readily available but they should be used with caution.[135,136] In addition, regular monitoring of endocrine function should begin around age 10, including that of the pituitary, endocrine pancreas, thyroid, parathyroid, adrenals, and gonads, since these organs may also be severely affected by iron overload.

Chelation Therapy

A pharmacologic approach using specific iron-chelating agents remains the only strategy for removing excess iron in transfusion-dependent patients. Several drugs with chelating properties have been synthesized or recovered from microorganisms. Many lack iron specificity or are inefficient; others cause significant toxicity. To chelate iron, the chelating agent must complex with all of the iron atom's six available coordination sites. Three general classes of iron chelators occur or have been synthesized: hexadentate (deferoxamine), bidentate (deferiprone), and tridentate (deferasirox) (Fig. 41.13). Only one hexadentate molecule is necessary to bind one atom of iron, but three molecules of a bidentate iron chelator bind one iron atom and two molecules of a tridentate chelator are required to bind one atom of iron. Chelatable iron is thought to be derived from the intracellular "labile iron pool"[137,138] and from the circulating nontransferrin-bound plasma iron.[139,140]

Benefits of Iron Chelation Therapy

More than 30 years of experience using iron chelation therapy with deferoxamine in thalassemia major patients have demonstrated that:

1. LICs can be maintained at normal or mildly elevated levels.
2. Hepatic fibrosis is slowed or prevented.
3. The risk of iron-induced cardiac disease, including heart failure and serious arrhythmias, is markedly decreased.
4. Normal growth and sexual development are common but not universal.
5. Long-term survival is substantially improved. These benefits are directly related to compliance and generally require the prolonged administration of daily iron chelation therapy.
6. Long-term safety and efficacy studies of the oral iron chelators deferiprone and deferasirox are ongoing, and new formulations are in development.

The excretion of excess iron must be facilitated by the use of iron chelation. There are three iron chelators in clinical use currently, one parenteral and the other two administered orally.

Deferoxamine

Deferoxamine mesylate is a naturally occurring hexadentate siderophore first isolated from cultures of *Streptomyces pilosus*, introduced as an iron chelator in 1960. Poorly absorbed from the gastrointestinal tract because of its high molecular weight, and with a short plasma half-life, it must be given parenterally by continuous infusion, either intravenously or subcutaneously. However, it is highly specific for iron and is associated with relatively low toxicity.[141] Deferoxamine enters cells, chelates iron, and appears in the serum and bile as the iron chelate, ferroxamine,[142] and is excreted through bile and in the urine.[143] Approximately one-half to two-thirds of the iron excreted in response to deferoxamine is in the stool, with the remainder in the urine.[144] These proportions vary from patient to patient and at different levels of iron overload, dose of deferoxamine, and endogenous erythropoietic activity.[145]

Iron excretion after the administration of deferoxamine is proportional to body iron stores. To achieve negative iron balance, the chelating agent must cause the daily excretion of 0.3 to 0.6 mg/kg of iron. Deferoxamine was initially administered by daily intramuscular injections of 0.5 g, which led to lower hepatic iron accumulation and fibrosis.[146,147] However, intramuscular injections proved to be too painful and, because of the limited dose administered, were insufficient to achieve negative iron balance. In the mid-1970s, it was demonstrated that iron excretion was markedly enhanced and negative iron balance was attained by continuous, prolonged 24-hour intravenous or 8- to 12-hour subcutaneous infusions of deferoxamine at 20 to 60 mg/kg/day.[148,149]

The typical regimen of subcutaneous infusions 5 to 6 nights a week was not only suboptimal because of the lack of 24-hour coverage, it was also extremely cumbersome. In addition, injection site pain, skin reactions, and occasionally abscesses often led to poor compliance. In patients who were poorly compliant with subcutaneous therapy, and with high iron burdens, intravenous continuous administration

in normal or higher doses was accomplished through an indwelling line. Continuous intravenous administration of deferoxamine is particularly useful for rapidly lowering the total iron burden and is used for reversal of cardiac morbidity (e.g., cardiac arrhythmias or left ventricular dysfunction). Doses above 50 to 60 mg/kg/day are not associated with increased iron excretion. Complications of indwelling catheters include infection and thrombosis, and this route of administration is a last resort.

Patients receiving aggressive chelation therapy with lower iron burdens may be more susceptible to toxicity. Neurosensory toxicity of deferoxamine is dose related and inversely correlated with body iron burden. Impairments of visual and auditory acuity are associated with high doses of deferoxamine relative to the iron load.[150] The ototoxicity is characterized by bilateral high-frequency hearing loss. The retinal toxicity is characterized by the loss of night and color vision, retinal atrophy, and cataract formation.[151] Patients receiving deferoxamine should undergo baseline and annual audiograms and ophthalmologic examinations. Deferoxamine should be discontinued if such abnormalities arise, with cautious reinitiation at lower doses when abnormalities improve or resolve. The risk of visual and auditory side effects can be minimized by adjusting the daily deferoxamine dose to the patients' serum ferritin level.[150] Impaired growth associated with growth plate deformities or metaphyseal rickets-like changes in the long bones and histologic evidence of cartilage dysplasia may occur in young children receiving deferoxamine.[152–154] Other, less common complications of deferoxamine include anaphylaxis, hypotension, allergic reactions, acute pulmonary disease, impairment of renal function, and infection.[155–161] Severe allergic reactions are rare, and desensitization has been achieved successfully in some patients.[157,158] Acute pulmonary disease and renal failure have occurred in a few patients receiving unusually high doses of deferoxamine by intravenous infusion.[159] The mechanism of this toxicity is unclear. One of the most serious complications of deferoxamine is an increased risk of infection with *Yersinia*, and mucor, iron-avid organisms which use deferoxamine as a siderophore. Deferoxamine can enhance the growth and virulence of these organisms, leading to colitis, abdominal abscesses, or sepsis.[160,161] The safety of deferoxamine during pregnancy has been inferred from case reports rather than formal studies. A summary of these case reports identified 11 women who received deferoxamine beginning in the first trimester and 33 women who used the chelator beginning in the second or third trimester.[161] None of the infants showed evidence of drug-related toxicity.[162]

There are data confirming that endocrine dysfunction was improved and cardiac disease was delayed or prevented with standard deferoxamine regimens.[163] Cardiac arrhythmias and congestive heart failure have reversed in some patients with standard or aggressive deferoxamine regimens, and life expectancy was significantly prolonged.[164–166] Intense 24-hour intravenous deferoxamine regimens of no more than 15 mg/kg/h were used to reverse early cardiac hemosiderosis, but these doses were associated with pulmonary toxicity resembling ARDS. More conventional doses of 50–60 mg/kg/day have improved left ventricular ejection fractions and prevented death in most patients.[167,168]

However, though regular chelation with deferoxamine has proven remarkably effective in reducing the transfusional iron burden, primarily because of its route of administration, it is now a second-line agent, or in addition to another chelator in more severely iron-overloaded individuals.

Deferasirox

Deferasirox (ICL670) is an orally active iron chelator that was identified by computer technology at Novartis Pharmaceuticals in the 1990s. It is a tridentate compound known as 4-(3,5-bis[2-hydroxyphenyl]-1*H*-1,2,4-triazol-1-yl)-benzoic acid,[169] wherein two molecules of deferasirox are required to bind one atom of iron. It has a high affinity for iron and a much lower affinity for copper and zinc. Deferasirox is orally bioavailable and is well absorbed by the gastrointestinal tract. It has a dose-dependent plasma half-life of 12 to 18 hours that allows for once-daily oral administration after fasting on an empty stomach.[170] Defarasirox was initially provided as dispersible tablets (Exjade) and administered as a suspension in water or apple or orange juice.[171] It is now available as a film-coated tablet (Jadenu) which does not need suspension, as well as granules which can be sprinkled on yogurt or applesauce for young children. This formulation has a lower prevalence of GI side effects and is better tolerated. Dosing for the dispersible tablets is 20 to 40 mg/kg/day, while for the film-coated tablet and sprinkles is 14 to 28 mg/kg/day. Iron excretion in response to deferasirox is largely via the bile and hence in the stool (90%) and far less in the urine (10%).[171]

Deferasirox is generally well tolerated. Self-limited mild gastrointestinal complaints and maculopapular skin rashes are the most common adverse events. Discontinuation of deferasirox is rarely required, but may be necessary if the GI upset is debilitating or patients develop symptoms suggestive of colitis. Mild increases in serum aspartate transaminase (ALT), alanine aminotransferase (AST), and creatinine, and intermittent proteinuria may also occur and thus monitoring for these at least once a month is recommended. Severe renal complications may occur in patients with preexisting renal disease, and such patients may need to be treated with an alternate chelator. Dose reduction, interruption, or discontinuation should be considered for elevations in serum creatinine. Deferasirox-induced changes in creatinine and renal hemodynamics are usually mild and reversible without progression over time.[172] Reports of pancytopenia have occurred in postmarketing reports, but mostly in patients with preexisting hematologic disorders such as MDSs that are frequently associated with BM failure.

Deferiprone

Deferiprone, 1,2-dimethyl-3-hydroxypyrid-4-one, is an orally active bidentate iron chelator that requires three molecules to bind one iron atom. It was synthesized in the late 1980s and was first tested in uncontrolled clinical trials at the Royal Free Hospital in London, hence the eponym L1.[173,174] It is readily absorbed by the gastrointestinal tract and has a plasma half-life of approximately 2 hours, hence it was originally dosed three times a day to provide continuous chelation coverage. Chelated iron is excreted predominantly in the urine (90%) and far less in the stool (10%). A large observational study demonstrated improvement in cardiac iron deposition with deferiprone treatment.[175] At doses of 75 mg/kg/day, deferiprone reduces or maintains iron stores, thereby achieving negative iron balance or iron balance in many regularly transfused patients.[176–184] However, some patients remain in positive iron balance and continue to accumulate iron during long-term therapy with this dose of deferiprone,[176,180,185] and higher doses up to 100 mg/kg/day may be more effective.[186]

Agranulocytosis occurs in 1% of patients and, although rare, remains the principal concern for patients receiving deferiprone. Milder neutropenia (absolute neutrophil count <1500 but >500) is more common and occurs in approximately 6% to 8% of patients. Severely depressed neutrophil counts represent a significant risk of sepsis and hospitalizations, and in some cases, administration of granulocyte colony-stimulating factor is required. Some reported deaths have been related to deferiprone-induced agranulocytosis or neutropenia. Regular weekly monitoring of blood counts during deferiprone therapy is recommended to detect the rare but important deferiprone-induced complications of neutropenia and agranulocytosis.[180–182,187] In cases where mild neutropenia develops, it may be safe to continue deferiprone therapy with more frequent monitoring of blood counts and clinical symptoms.[188]

Other side effects of deferiprone include gastrointestinal complaints, mostly nausea and some vomiting that occur in approximately 33% of patients and usually resolve without specific intervention. Arthropathy with arthralgias and some joint effusions occur in approximately 15% of patients. The incidence of joint symptoms varies widely among various studies but may be severe enough to require reduction or interruption of chelation therapy.

Abnormal liver function tests may occur gradually or suddenly and in the absence of other causes of hepatic dysfunction. These elevations may return to baseline values with the interruption of deferiprone followed by reinitiation beginning with lower doses and close monitoring of liver function tests. Progressive liver disease attributed to deferiprone has not been reported, and initial concerns about drug-induced hepatic fibrosis have not been substantiated by subsequent studies.[177,179,189,190]

Given the need for three doses a day, and the impact on compliance, deferiprone is used mainly as a second-line agent, unless there is a dose-limiting toxicity with deferasirox. It is also used in combination with either of the other chelators. Combination regimens with deferoxamine also reduce iron stores or prove effective in restoring negative iron balance in some of these patients.[191–193] Enhanced urine and stool iron excretion in thalassemia patients using both deferoxamine and deferiprone have suggested an additive effect postulated by the shuttle hypothesis, that is, deferiprone may chelate intracellular labile iron and shuttle it to deferoxamine.[194] Some studies have also suggested that deferiprone alone or in combination with deferoxamine may be more effective than deferoxamine in removing iron from the heart, improving cardiac function, and preventing iron-induced cardiac disease.[122,184,195–198] A prospective randomized study comparing the combination of deferiprone at 75 mg/kg/day and deferoxamine at 40 to 50 mg/kg/day with deferoxamine alone demonstrated that the combination therapy more rapidly reduced hepatic and cardiac iron stores than deferoxamine alone.[199] Schedules for combination therapy vary but have usually included 5 to 7 days of deferiprone and 2 days of subcutaneous deferoxamine weekly. Intensive combined chelation therapy has been reported to reverse both cardiac and endocrine complications of thalassemia major.[200] Combination with deferasirox has also been reported in a number of case series with good efficacy overall.[201–204]

A twice daily preparation of deferiprone is now available.[205] This should improve compliance for those who were previously on three-times-a-day dosing and offer an alternative to deferasirox for those who continue to have some GI symptoms on that agent. A liquid formulation of deferiprone is also available and is particularly advantageous in pediatric patients.

Combination Chelation Therapy

Many different combination regimens of these chelators have been used for patients with severe iron overload, often tailored to whether the overload is more systemic or more cardiac. Deferiprone-containing combinations are more frequently used in cardiac overload than in systemic overload.

A review of chelation guidelines may be found at the Cooley's Anemia Foundation website[206] and at the Thalassaemia International Federation website.[207]

All of the iron chelators—deferoxamine, deferiprone, and deferasirox—have proved to be safe and effective in non-transfused thalassemia intermedia.[208–210]

Complications of Thalassemia and Their Management

The thalassemia syndromes have a myriad of complications both related to the disease as well as its treatment. The complications of the disease are all related to the underlying IE as a result of the imbalance in α- and β-globin production. Once appropriate treatment with regular transfusions is begun, and IE is adequately suppressed, those complications are now replaced by potential adverse effects of transfusion therapy, the most important long-term complications being related to transfusional iron overload. Individuals with thalassemia intermedia, who are not regularly transfused, that is, NTDT patients, will continue to have complications related to IE, which will be described in this section (Fig. 41.14).

Complications Related to Ineffective Erythropoiesis

Individuals with more severe IE have more significant anemia, and as a result may have growth retardation, chronic fatigue and malaise, bone pain, and worsening splenomegaly and still develop iron overload. Splenectomy is often performed when there is a component of hypersplenism contributing to worsening anemia. Gallbladder disease from increased red cell turnover and the development of

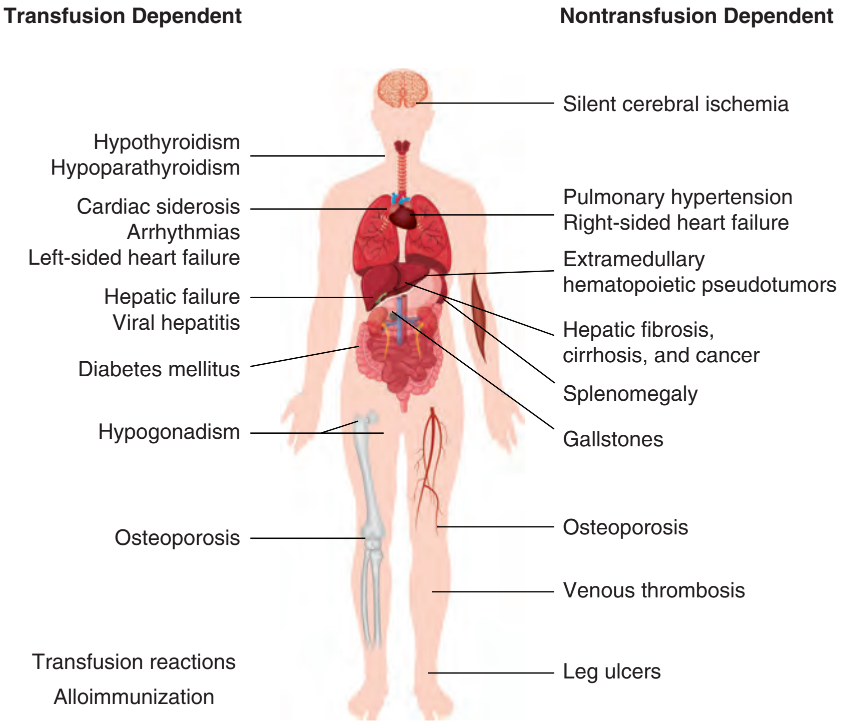

Figure 41.14 Complications of thalassemia—mainly related to iron overload in transfusion-dependent thalassemia, and related to the systemic effects of ineffective erythropoiesis in non-transfusion-dependent thalassemia.

pigment gallstones is quite common. Progressive EMH may result in paraspinal nodules as described previously. Thromboembolic events represent a major complication of thalassemia intermedia, occurring in 10% to 34% of patients.[211,212] These events include stroke, pulmonary embolism, portal vein thrombosis, and deep vein thrombosis of the legs. Splenectomy is a risk factor for thromboembolic events in patients with thalassemia intermedia, resulting in thrombocytosis and allowing the prolonged circulation of damaged RBCs that generate increased amounts of thrombin.[211] Clinical manifestations including the development of chronic, non-healing leg ulcers from poor perfusion and the effects of arterial endothelial damage. A possible hypercoagulable state may contribute to other manifestations of vascular disease such as cerebral infarcts and development of pulmonary hypertension, complications which commonly occur in patients with thalassemia intermedia with the latter being the primary cause of congestive heart failure.[213] Some investigators consider the risk of thromboembolic events after splenectomy for thalassemia intermedia to be sufficiently high to warrant short-term anticoagulation in the perioperative period and during pregnancy.[211] Oral contraceptives should be used with extreme caution, if at all. Interestingly, known genetic thrombophilias in other populations like factor V Leiden, the prothrombin gene mutation 20210, and MTHFR C677T mutations have not been associated with thrombotic risk in this population.[214]

Extension of hematopoietic tissue beyond the confines of the bones occurs in patients with thalassemia intermedia as a result of the intense erythropoiesis. This complication occurs less frequently in patients with thalassemia major because of the partial suppression of erythropoiesis by regular transfusions. Masses of extramedullary hematopoietic tissue develop in the spinal epidural space, thorax, cranium, pelvis, and elsewhere.[215–226] These masses may be detected as incidental findings on imaging studies of the chest or abdomen.[217–223] In other instances, the masses produce symptoms by compressing neighboring structures. For example, patients with extramedullary hematopoietic masses may develop paraplegia from spinal cord compression or loss of visual acuity or visual fields caused by optic nerve compression.[216,219,225,226] Additional clinical presentations of hematopoietic masses include pleural effusions and upper airway obstruction.[221,222,224] Initiation of regular transfusions for patients with thalassemia intermedia or intensification of the ongoing transfusion program for patients with thalassemia major reduces the size of extramedullary hematopoietic masses and helps to prevent recurrences (see Tables 41.4 and 41.5). Additional bone changes are described subsequently.

Even in the absence of regular transfusions, many patients develop progressive iron overload because of increased absorption of dietary iron induced by IE and, in many cases, the intermittent administration of RBC transfusions. By the third or fourth decade of life, and occasionally even the second, the total iron burden may attain the levels seen in transfusion-dependent patients.[227] Ferritin levels underestimate the degree of tissue iron loading in thalassemia intermedia, and assessment of LIC is more helpful in determining the need for chelation therapy.[135] Iron overload may result in diabetes and endocrine disturbances, typically by the fourth decade of life, though cardiac deposition is relatively rare in true thalassemia intermedia individuals.

Skeletal Changes

With improved survival in patients with thalassemia major, the problem of bone disease has assumed greater importance.[228] Approximately 50% to 80% of older thalassemia patients have an osteoporosis-osteopenia syndrome.[229,230] The pathogenesis of bone disease is multifactorial including expansion of the medullary cavity due to IE, with subsequent thinning of the cortices, endocrinopathy, and iron overload.[231] The widespread prevalence of osteoporosis in patients with thalassemia major was first observed across all ages in 1995.[232] Subsequently, others reported a high frequency of abnormal *Z* scores in pediatric, adolescent, and adult patients. Abnormal bone mineral density has been reported in older studies of pediatric and adolescent patients with thalassemia major,[233–235] though it is less likely that well transfused and chelated patients will have these complications at the same frequency. Vertebral fractures are associated with osteoporosis and cause significant morbidity in this population. Lumbar and thoracic vertebrae fractures are present in over 30% of thalassemia patients over the age of 30 years.[236,237] The Thalassemia Clinical Research Network noted the overall fracture prevalence of 12% in a contemporary sample of 702 patients with α - and β-thalassemia. The fractures occurred more frequently in thalassemia major (17%) and intermedia (12%) compared with β-E (7%) and α-thalassemia (2%). Fracture prevalence increased with age and with sex hormone replacement therapy.[238] An observational study by the Thalassemia Clinical Research Network has demonstrated a high prevalence of low bone mass across all the thalassemia syndromes, including β-thalassemia major, intermedia, β-E, HbH, H-Constant Spring, and homozygous α-thalassemia, which progresses with aging. In addition, increased serum and urine markers of bone turnover have been described in thalassemia patients with osteoporosis, which correlate with low dual-energy X-ray absorptiometry scores and improve with bisphosphonate therapy.[239] It remains unclear if different chelation therapies and transfusions can alter the progression of osteoporosis.[240] Bisphosphonates have been used with varying success to correct the osteopenia, not always being successful given the complex pathophysiology of the disease.[241–243] Zinc supplementation may also improve bone density in younger patients with thalassemia.[244]

Skeletal abnormalities are less common in patients receiving regular RBC transfusions but may still occur as a result of partially unchecked IE and expansion of the erythroid BM.[245] These cause widening of the BM space and thinning of the cortex, with consequent osteoporosis.[232,246] Changes in the skull and facial bones, including expansion of the frontal bone with prominent frontal bossing, may occur before the initiation of transfusion therapy. Radiographs reveal the diploic spaces to be widened. At first, the skull has a granular appearance, but later perpendicular bony trabeculae appear, giving the classic “hair on end” or “crewcut” appearance (Fig. 41.15). Marked overgrowth of the maxilla results in severe malocclusion, jumbling of the upper incisors, and prominence of the molar eminences.[247] These bone changes produce the classic thalassemic facies. Additional skeletal changes are observed in the metacarpals, metatarsals, and phalanges, where expanded medullary cavities produce a rectangular and then a convex shape. Irregular fusion of the epiphyses of the proximal humerus results in characteristic shortening of the upper arms.[248,249] Marked osteoporosis and cortical thinning may predispose to pathologic fractures of the extremities and compression fractures of the vertebrae (Fig. 41.16).

Several abnormalities in the ribs may occur, including notching and osteolytic lesions.[245,250] The ribs become very wide, especially at

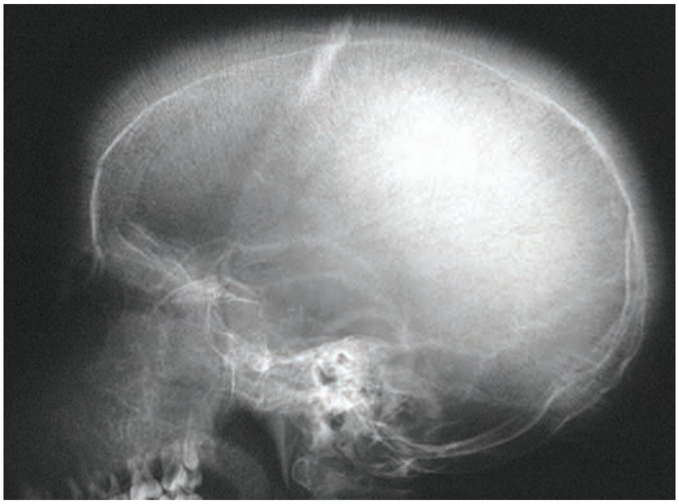

Figure 41.15 MARKED EXPANSION OF THE DIPLOEIC SPACE IN THE SKULL BONES WITH THE “HAIR ON END” OR “CREW CUT” APPEARANCE ON X-RAY.

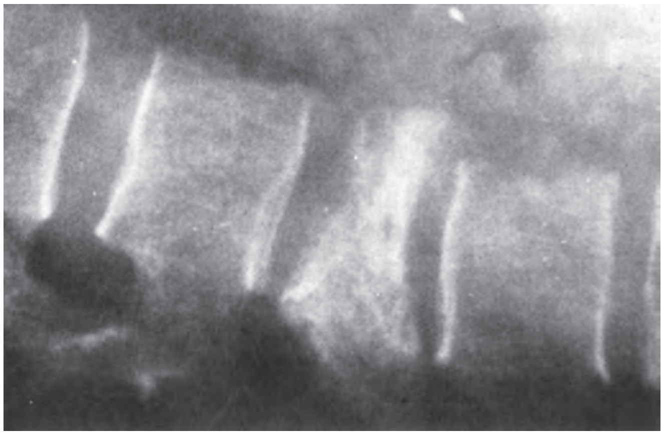

Figure 41.16 COMPRESSION FRACTURE OF L2 VERTEBRA IN A PATIENT WITH SEVERE β-THALASSEMIA. *(From Pearson HA, Benz EJ Jr. Thalassemia syndromes. In: Miller DR, Baehner RL, McMillan CW, eds. Smith's Blood Diseases of Infancy and Childhood. 5th ed. St. Louis: CV Mosby; 1984:439.)*

the points of their attachment to the vertebral column. BM masses may extrude from these sites, creating the appearance of paravertebral masses and compressing the spinal cord.[251]

Endocrinopathies

The endocrine organs are more susceptible to iron deposition and the resulting dysfunction can lead to significant morbidity. These complications are seen at higher frequencies in poorly chelated individuals and with improved chelation compliance with the oral agents it is anticipated that the incidence of these complications will decline. Regular monitoring for these complications is recommended, especially in those individuals with a history of more significant iron overload and poor chelation compliance.

Growth. Growth retardation, including skeletal and dental deformities,[252] was common even in young children until the use of hypertransfusion regimens was instituted. With the correction of the severe anemia, growth was initially restored to relatively normal during the first decade of life, unless heavy iron deposition in the pituitary resulted in growth hormone deficiency early. Without appropriate iron chelation therapy, the adolescent growth spurt is often delayed or absent; most patients, even those well maintained by transfusion, may not attain normal stature, partly because of iron-induced damage to the anterior pituitary.[43,253,254] Menarche is frequently delayed. Breast development may be poor, and many female patients have primary or secondary amenorrhea. Boys are frequently immature, with sparse facial and body hair. Although spermatogenesis may be normal at least initially, libido is often decreased as a result of decreased testosterone secretion. An older multicenter study of 250 adolescent patients in northern Italy showed that despite hypertransfusion and 7 to 10 years of deferoxamine iron chelation therapy, two-thirds of male patients and one-third of female patients older than 14 years of age were two standard deviations or more below the mean for height.[255] Many adolescents between 12 and 18 years of age lacked any secondary sexual changes of puberty. However, the mean serum ferritin level in the entire group was 3500 ng/mL, indicating persistence of a high level of excess iron burden in most of this group.

Regular chelation therapy started early in the first decade of life frequently allows a normal onset of puberty and development of secondary sexual changes.[256] If necessary, administration of recombinant human growth hormone in conventional doses increases height velocity in patients with growth hormone deficiency.[257,258] Normal or higher doses of recombinant human growth hormone increase growth velocity in patients with normal growth hormone reserve but low levels of insulin-like growth factor I.[259,260] For patients with a functional hypothalamic-pituitary axis, treatment with gonadotropin-releasing hormone may induce pubertal changes.[261] In others, administration of sex steroids is necessary to induce secondary sexual characteristics.

Diabetes. Abnormal carbohydrate metabolism is common in older patients with thalassemia major. Prepubertal children usually have normal glucose metabolism, but pubertal patients exhibit impaired responses to glucose load. Higher than normal insulin levels despite normal glucose levels are also encountered during puberty.[262] The defect in these patients appears to be related to insulin resistance, with insulin deficiency developing later in the progression to diabetes. Rates of diabetes are reported close to 6% to 8%.[263] Diabetes occurs more frequently in patients with hepatitis C and hepatic dysfunction.[264–266] Oral hypoglycemic agents have been used to regulate hyperglycemia and may reduce the rate of further deterioration of glucose metabolism.[267] It is important to keep in mind that the conventional HbA1C monitoring is not reliable in individuals who are regularly transfused since it measures levels in red cells which have been stored in high concentrations of glucose for variable periods of time. Hence an oral glucose tolerance test is recommended for monitoring for this complication in individuals at risk.

Thyroid and parathyroid disease. Laboratory findings of hypothyroidism and hypoparathyroidism are present in approximately 14% of patients with thalassemia major.[268–272] Though clinical findings associated with these deficiencies are uncommon, replacement therapy is recommended.[273]

Liver and Gallbladder

Hepatomegaly occurring before the initiation of transfusion therapy in severely affected patients is primarily a consequence of EMH. With the amelioration of the anemia, the liver diminishes in size. However, as transfusion therapy continues, iron accumulation provides a new reason for hepatomegaly and resultant liver injury. Iron deposition, first present in the Kupffer cells, ultimately engorges the parenchymal cells, resulting in an appearance that is indistinguishable from that of idiopathic hemochromatosis.[274–276] The hepatocellular injury of iron overload may be attributable to the liberation of hydrolases resulting from initiation by the ferrous form of iron and peroxidative damage of lysosomal membrane lipids.[277] Fibrosis is usually followed by cirrhosis and an increased risk of hepatocellular carcinoma. The risk of liver damage and the rate of progression may be increased by the concomitant presence of excessive iron with viral hepatitis, previously an issue in these patients receiving regular transfusions, but with improved screening of blood products it is not such an issue anymore in higher-income countries of the world.

Regular chelation therapy is the key to maintaining normal or near-normal hepatic iron concentrations and preventing iron-induced hepatic fibrosis and cirrhosis. Treatment with deferoxamine slows or prevents iron-induced liver damage and may reduce the severity of preexisting fibrosis in some cases.[146,278,279]

Pigmentary gallstones caused by high levels of bilirubin production from red cell turnover are found in an increasing number of patients older than 4 years of age. Two-thirds of patients have multiple calcified bilirubinate calculi after the age of 15 years.[280] Cholecystectomy is not routinely indicated unless biliary colic or obstructive jaundice has occurred.

Heart

Cardiac abnormalities are important causes of morbidity and mortality in patients with thalassemia major. Cardiomegaly secondary to anemia is almost always present in untransfused children. Before the availability of chelation therapy, myocardial hemosiderosis and serious iron-induced cardiac diseases were inevitable during the second decade, usually the cause of mortality. These problems still occur often in older patients with thalassemia who are poorly compliant with chelation therapy, and heart disease, usually in the form of cardiac failure or serious arrhythmias, remains the most common cause of death in patients with thalassemia major.[281,282]

Left-sided heart failure predominates in patients with thalassemia major and is characterized by dyspnea and orthopnea.[283] Right-sided heart failure is less common but may be the presenting cardiac finding in older patients with more severe iron overload. Diastolic dysfunction develops first, with few symptoms, but if this progresses to systolic dysfunction, the resulting heart failure is acute in onset and very difficult to treat.[284,285] Acute myocarditis, which occurs in approximately 5% of patients with thalassemia, is frequently followed by acute or chronic heart failure.[286]

Early electrocardiographic abnormalities include a prolonged P–R interval, first-degree heart block, and premature atrial contractions. Later, ST-segment depression and ventricular ectopic beats constitute ominous indicators of myocardial damage. Periodic evaluation of cardiac function is essential to detect iron-induced heart disease and to identify patients who will benefit from more intensive chelation therapy (see later discussion). Unfortunately, by the time cardiac results of studies such as echocardiography and 24-hour rhythm monitoring become abnormal, clinical heart disease is imminent. Whether assessment of cardiac iron by MRI using T2* or other measures can better anticipate the development of clinical heart disease is currently under investigation.

In the absence of intensified chelation therapy, ventricular dysfunction progresses rapidly to chronic refractory congestive heart failure, and arrhythmias become increasingly difficult to control. In the past, death usually occurred within 1 year of onset of heart failure. More recent data demonstrate a survival rate of 48% at 5 years.[283] Survival is notably poorer in patients with heart failure after myocarditis or with heart failure accompanied by arrhythmias.[286]

In addition to standard therapy for heart failure and arrhythmias, including angiotensin-converting enzyme inhibitors, β-blockers, diuretics, and antiarrhythmic agents, the pretransfusion Hb level should be maintained between 10 and 12 g/dL. The volume of transfused RBCs should be reduced as needed to prevent acute fluid overload. Because the iron-overloaded myocardium has little capacity to improve its performance unless excess iron is removed, intensive chelation therapy is a critical part of the management of heart disease in patients with thalassemia. Several studies have shown that heart failure can be reversed in many patients with the use of continuous treatment with deferoxamine.[164,287,288] The benefits of this approach may derive from the reduction in cardiac iron stores, the prevention of acute toxicity from nontransferrin-bound iron, or a combination of these two mechanisms. Data suggest that deferiprone may be more effective than deferoxamine in reducing the cardiac iron load and treating iron-induced cardiac disease, perhaps because of deferiprone's ability to enter cardiac cells more rapidly than deferoxamine.[122,195] On the other hand, it may not be as effective in reducing hepatic iron content.[122,195,289] Deferasirox treatment for 1 to 2 years has also been shown to reduce cardiac iron and improve cardiac MRI T2* in patients with transfusional iron overload.[290,291] In patients who have undergone hematopoietic stem cell transplantation (HSCT), improvements in left ventricular contractility and diastolic function accompany the removal of excess iron by phlebotomy.[292] Heart transplantation and combined heart-liver transplantation have been performed successfully in patients with end-stage cardiac disease.[293–295]

Sterile pericarditis occurs in some patients with massive iron overload.[296] Although pericarditis is most often attributed to hemosiderosis, an association with β-hemolytic streptococcal infection and other infectious agents has also been suggested.[297] Therapy usually consists of bed rest, treatment of infection, management of superimposed congestive heart failure, and the use of salicylates or corticosteroids. Occasionally, pericardiectomy may be indicated.

Lungs

Mild abnormalities of pulmonary function are common in patients with thalassemia but rarely cause clinical problems.[298,299] Some patients exhibit primarily restrictive defects[300,301]; others experience mild to moderate small airway obstruction and hyperinflation.[302–304] Most patients have a decreased maximal oxygen uptake and anaerobic threshold; these do not normalize after transfusion.[305] Postsplenectomy thrombocytosis and other prothrombotic changes can predispose to pulmonary vascular occlusion and pulmonary hypertension, more so in NTDT patients compared with well transfused TDT patients.[211,306–309] Treatment with high doses of the iron chelator deferoxamine may also be associated with acute deterioration of pulmonary function.[159,160]

Kidneys

The kidneys are frequently enlarged, partly because of EMH and partly because of marked dilation of the renal tubules.[310] The urine is often dark brown, reflecting the excretion of products of heme catabolism.[311] The urine also contains large amounts of urates and uric acid.

The Thalassemia Clinical Research Network studied the prevalence of renal abnormalities in patients with thalassemia major and thalassemia intermedia receiving deferoxamine chelation. One-third of thalassemia patients who were not regularly transfused had abnormally high creatinine clearance. Regular transfusions were associated with a decrease in clearance ($P = .004$). Almost one-third of patients with thalassemia had hypercalciuria, and regular transfusions were associated with an increase in the frequency and degree of hypercalciuria ($P < .0001$). Albuminuria was found in more than half of patients but was not consistently associated with transfusion therapy. In summary, renal hyperfiltration, hypercalciuria, and albuminuria are common in patients with thalassemia.[312] Higher transfusion intensity is associated with lower creatinine clearance but more frequent hypercalciuria.[313]

Deferasirox may also cause some renal dysfunction, ranging from mild proteinuria to a reduction in glomerular filtration rate (GFR) and increase in creatinine. Patients receiving this agent for chelation should be carefully monitored.[314]

Spleen and Splenectomy

Splenomegaly is common in thalassemia. It is initially a result of EMH, and once regular transfusions are initiated, will regress to near normal. However, in NTDT patients with moderate anemia, it may continue to enlarge in an attempt to compensate for the degree of anemia. Over time, very enlarged spleens may also become hypersplenic leading to the decision to splenectomize. After splenectomy, there may be some improvement in the Hb level, but this may come at a price—the development of vascular complications, as discussed later. In TDT, with continuing regular transfusions, mild or moderate splenomegaly may be associated with findings of hypersplenism, including thrombocytopenia, neutropenia, and increasing anemia. The usual indication for splenectomy in regularly transfused patients is a progressive increase in transfusion requirements caused by hypersplenism. The transfusion requirements, and therefore the rates of iron loading, of splenectomized patients are often considerably less than those of patients whose spleens are intact.[289,315–317] A transfusion requirement of more than 180 to 200 mL/kg/year of packed RBCs usually represents excessive RBC requirements.[316,317] For such patients, a 25% to 60% reduction in transfusion requirements after splenectomy is generally predictable. Before attributing increased transfusion requirements to hypersplenism, it is important to look for other causes, such as RBC alloimmunization or a change in the hematocrit of the units of donor blood. Surgery should be deferred until after 5 years of age whenever possible to maximize the development of the humoral immune system, because of the greater risk of postsplenectomy sepsis in younger patients. For well-transfused and well-chelated patients, splenectomy may have little benefit, and some centers have noted a significant decline in the number of patients undergoing splenectomy in recent years.

Laparoscopic splenectomy has proved safe for patients with thalassemia and has dramatically shortened the recovery time compared with open procedures.[318] Partial splenectomy and partial dearterialization of the spleen have been suggested as alternative approaches to reducing blood requirements without incurring the risk of sepsis.[319–321] The long-term benefits of this approach remain uncertain. Therapeutic embolization of the spleen avoids the need for surgery,[322–324] but this approach is frequently associated with postprocedure pain and fever and does not permit the removal of accessory spleens.

After splenectomy, striking thrombocytosis may occur, which may require thrombosis prophylaxis or platelet deaggregating agents.[325] Increased numbers of nucleated RBCs appear in the blood, and the presence of many RBCs containing inclusion bodies composed of precipitated α-globin chains can be demonstrated by staining with supravital staining. The release of abnormal red cells from the marrow as a result of IE, with the lack of a splenic filter, adds an additional risk. The latter, combined with thrombocytosis, results in a coagulopathy[326] which may lead to significant vascular disease, particularly the development of cerebral infarcts and pulmonary hypertension. This is more of an issue in NTDT intermedia patients than well transfused patients in whom the IE is adequately suppressed.[327–329] However, this is a major rationale for the declining use of splenectomy.

Splenectomy should generally be reserved for patients with excessive transfusion requirements from hypersplenism and difficulty controlling iron overload. A large spleen alone does not usually cause significant clinical problems and should rarely, if ever, be the sole reason for splenectomy. Patients with thalassemia major are at significant risk for the development of overwhelming, often fatal, infection after splenectomy (postsplenectomy sepsis syndrome).[330] The problem is most common in young children. *Streptococcus pneumoniae* causes two-thirds of cases; *Hemophilus influenzae* type B and *Neisseria meningitidis* account for most of the remaining infections. Typically, there is a fulminant clinical course, proceeding from mild fever and headache to hyperpyrexia, prostration, shock, and death within 6 to 12 hours. Before splenectomy, polyvalent pneumococcal, meningococcal, and *H. influenzae* vaccines should be administered if they have not been given earlier in life.[331,332] Prophylactic oral penicillin therapy, 250 mg twice daily, is generally used as prophylaxis against postsplenectomy infection in patients with thalassemia. However, the optimal duration of penicillin prophylaxis remains unknown, and compliance is frequently inadequate.[333] Although the risk of postsplenectomy sepsis decreases with age, it does not disappear, and fatal pneumococcal sepsis has occurred many years after removal of the spleen.[334]

Immunization against the most common pathogens before splenectomy, prophylaxis with antibiotics, and early assessment of fever after splenectomy have dramatically reduced the incidence of fatal postsplenectomy sepsis.

Survival in Patients With Thalassemia Major

Improved transfusion therapy and the consistent use of iron chelation therapy have extended the life span of patients with thalassemia major.[83,281,282,335] In a multicenter study of 1079 patients in Italy, the probability of survival to age 20 years was 96% for patients born between 1975 and 1979, the time at which chelation therapy became a regular part of the overall management of thalassemia major (Table 41.3).[281] In contrast, the probabilities of survival at 20 years of age were only 61% and 69% for those born in the periods of 1960 through 1964 and 1965 through 1969, respectively. Other investigators have shown that survival or prevention of life-threatening complications is strongly related to good chelation therapy, assessed either by compliance or by control of iron stores (Fig. 41.17).[125,168,282] The importance of good compliance with chelation therapy is further demonstrated by data from the United Kingdom showing that the probability of survival for the 1975 through 1984 birth cohort is to date not substantially different than the probability of survival for the 1965 through 1974 birth cohort.[335] The researchers attribute this poorer than expected survival rate, despite the availability of deferoxamine, to a lack of adherence to the recommended schedule of treatment with this chelator.

TABLE 41.3 **Survival by Birth Cohort at Different Ages of Patients With Transfusion-Dependent Thalassemia**

Patient Age (Years)	Cohort (%)		
	1970–1974	1975–1979	1980–1984
10	98 (96–99)	98 (96–99)	99 (95–100)
15	95 (92–97)	97 (94–98)	98 (93–100)
20	89 (85–92)	96 (93–98)	
25	82 (77–86)		

Data from Borgna Pignatti C, Rugolotto S, De Stefano X, et al. Survival and disease complications in thalassemia major. *Ann N Y Acad Sci.* 1998;850:227.

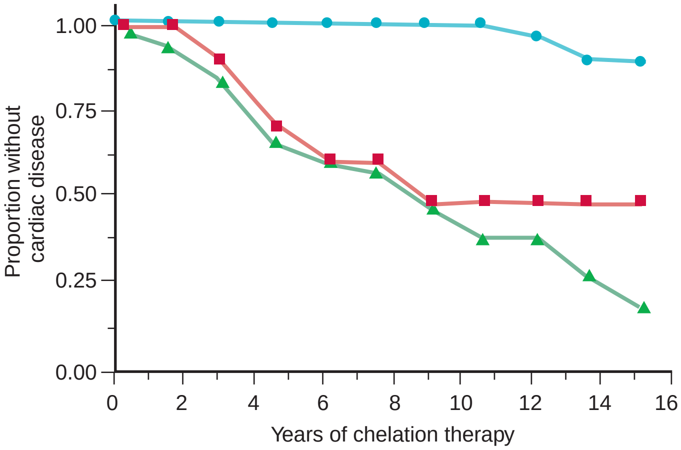

Figure 41.17 SURVIVAL WITHOUT CARDIAC DISEASE IN PATIENTS WITH THALASSEMIA MAJOR TREATED WITH DEFEROXAMINE ACCORDING TO THE PROPORTION OF SERUM FERRITIN MEASUREMENTS EXCEEDING 2500 ng/mL. The *circles* show cardiac disease-free survival among patients in whom less than 33% of ferritin measurements exceeded 2500 ng/mL; *squares* show survival among patients in whom 33% to 67% of ferritin measurements exceeded 2500 ng/mL; and *triangles* show survival among patients in whom more than 67% of ferritin measurements exceeded 2500 ng/mL. *(Adapted from Olivieri NF, Nathan DG, MacMillan JH, et al. Survival in medically treated patients with homozygous beta-thalassemia. N Engl J Med. 1994;331:574.)*

Consistent compliance with chelation to maintain a near-normal iron balance is undoubtedly the key to preventing complications in regularly transfused patients. Currently, with the advances in management of thalassemia, including a safer blood supply, lower rates of alloimmunization, oral chelators, improved methods of quantifying organ iron and tailoring chelation regimens, it may be fair to say that TDT individuals who are optimally managed with transfusions and chelation should anticipate near normal lifespans.

Chronic Care of the Adult Patient With Thalassemia

Adults with TDT syndromes are living longer into adulthood, with some approaching their seventh decade of life. It is likely in the coming decades that these patients will have improved life expectancies related to safer transfusion practices, improved screening of the blood supply, and better oral iron chelation medications. Therefore, the thalassemia patient born in the current era may expect to spend the majority of their life as an adult.

TABLE 41.4 Nontransfusion-Dependent Thalassemia Screening Recommendations

Test Name	Measurement	Frequency
MRI with T2* liver iron content	Liver iron	Every 1–2 years
MRI with T2* cardiac iron content	Cardiac iron	Every 1–2 years
Ferritin	Total body iron	Every 3-6 months
History and physical exam	General health, medication compliance	Every 3–4 months
Echocardiogram	Pulmonary hypertension TRV	Every 1–2 years
Liver function panel	Liver failure, hepatitis	Every 3-6 months
Liver ultrasound (if LIC >5 persistently)	Cirrhosis	Annually
AFP (if >40 or presence of clinical cirrhosis)	Hepatocellular carcinoma	Annually
Hepatitis B, C serologies (if receiving blood transfusions)	Hepatitis B and C viral infection/exposure	Annually
Free T4, TSH	Thyroid function	Annually
Calcium, phosphate, vitamin D	Parathyroid function	Annually
Fasting blood sugar/oral glucose tolerance test	Diabetes mellitus screening	Annually
DEXA	Bone mineral density	Annually

ACTH, Adrenocorticotropic hormone; *AFP*, α-fetoprotein; *DEXA*, dual-energy X-ray absorptiometry; *LIC*, liver iron concentration; *MRI*, magnetic resonance imaging; *TRV*, tricuspid regurgitant velocity; *TSH*, thyroid stimulating hormone.

TABLE 41.5 Transfusion-Dependent Thalassemia Screening Recommendations

MRI with T2* liver iron content	Liver iron	Every 1 year
MRI with T2* cardiac iron content	Cardiac iron	Every 1–2 years
Ferritin	Total body iron	Every 3 months
History and physical exam	General health, medication compliance	Every 3 months
Echocardiogram (if cine MRI not able to provide adequate information, or in years when cardiac MRI not done)	Pulmonary hypertension TRV	Every 1–2 years
Liver function panel	Liver failure, hepatitis, deferasirox toxicity	Every month
AFP (if > 40 or presence of clinical cirrhosis)	Hepatocellular carcinoma screening	Annually
Hepatitis B, C serologies	Hepatitis B and C viral infection/exposure	Annually
Free T4, TSH	Thyroid function	Annually
Calcium, phosphate, vitamin D	Parathyroid function	Annually
Fasting blood sugar/oral glucose tolerance test	Diabetes mellitus screening	Annually

There is currently limited expertise among adult hematologists in the management of adult thalassemia patients. Transition plans are essential for all pediatric patients as they enter adulthood, so that they may receive age-appropriate care. Transition is especially important in thalassemia, as they require the regular uninterrupted schedule of transfusions and chelation monitoring. Future efforts should be initiated to improve the care of adult patients with thalassemia, including understanding the pathology of the disease and training new generations of hematologists with an understanding of thalassemia syndromes.

Screening tests are also an important component of ongoing care in thalassemia. Currently, the most common cause of mortality in adults with thalassemia is related to cardiac disease and arrhythmias. These patients also have other chronic illnesses including cardiomyopathy, hepatic disease, endocrinopathies, osteoporosis, hypogonadism, pulmonary hypertension, and ongoing infectious risk from splenectomies. Recommended screening tests are shown in Tables 41.4 and 41.5, based on recommendations from the Thalassemia International Federation.[207] Regular follow-up with an internal medicine primary care physician is also recommended to make sure adults are aware of current screening and treatment guidelines applicable to the general population, for example age-appropriate cancer screening, an area where adult patients may not have previously been referred because of historically shorter lifespans.

Hematopoietic Stem Cell Transplantation

The only curative treatment available for thalassemia currently is HSCT. The current status of HSCT in general is discussed further in Chapters 105–107. There is now extensive experience with transplantation, with several thousand patients having undergone the treatment.[336] Historically, risk classification was based on three criteria: hepatomegaly, the degree of portal fibrosis, and the degree of iron overload.[337] In class 1 without adverse factors, the overall survival rate is 95%, and the event-free survival rate (without thalassemia) is 90%; class 2 patients with one or two risk factors have an 85% survival and an 81% event-free survival; and class 3 patients with all three risk factors have only 64% and 62% overall and event-free survival rates, respectively (Fig. 41.18).[337] Advances in conditioning regimens have considerably improved the outcome of class 3 patients who are younger than 17 years of age. Preparatory chemotherapeutic regimens to enhance immunosuppression and eradicate thalassemic clones using hydroxyurea, azathioprine, fludarabine, busulfan, and cyclophosphamide have increased the survival rate of class 3 patients to 93%; the rejection rate fell to 8%.[338] These favorable results have not been reproduced in the older, more heavily iron-overloaded patients who remain high risk for transplant-related mortality.[339]

While the criteria from the above classification are still relevant, currently, outcomes of HSCT in thalassemia are mostly dependent on two critical considerations: (a) the characteristics of the donor and (b) the preexisting morbidities in the recipient. The outcomes are superior when the donor is a matched relative, typically a sibling.[340] Although other donor types have been used in the clinical trial setting, outcomes are inferior from matched unrelated donors or any mismatched donor, including a haploidentical donor. However, over the years, results have improved quite significantly. In view of the available evidence, stem cell transplantation from a partially human leukocyte antigen (HLA)-matched relative is not routinely advisable, although it may be considered in extreme situations when transfusion support is impossible or life threatening when a patient is completely noncompliant with any type of iron chelation therapy. Additionally, alternative

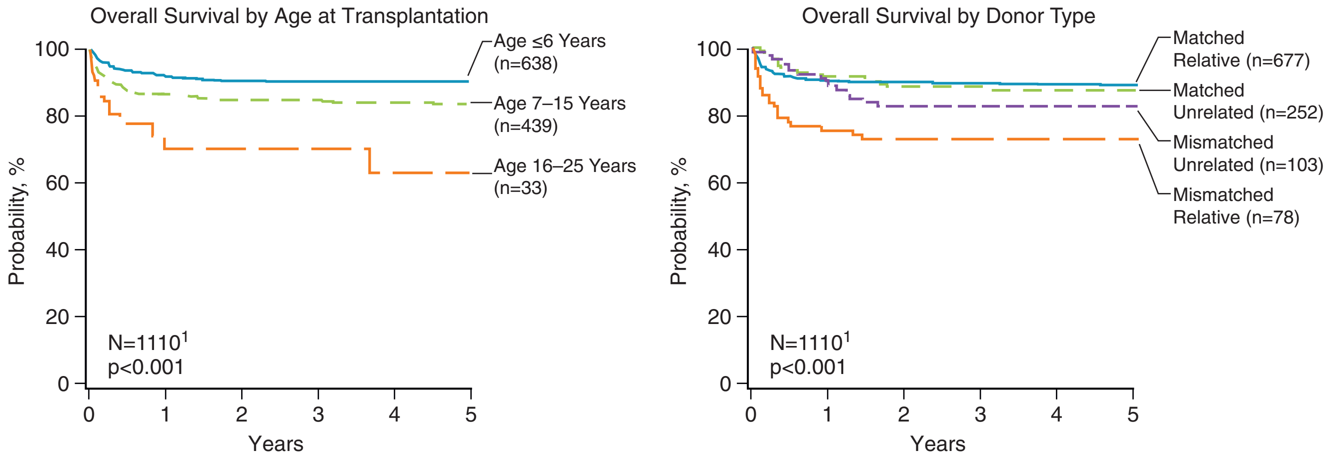

Figure 41.18 FAVORABLE OUTCOMES FOLLOWING ALLO-HSCT ARE ACHIEVED IN YOUNGER PATIENTS WITH HLA-MATCHED RELATED DONOR. The greatest 5-year probability of overall survival was observed in patients ≤ 6 years of age or who had an HLA-matched related donor.[1] Only a minority of patients with TDT undergo allo-HSCT with the majority of those being less than 14 years old with an HLA-matched sibling donor, well controlled iron, and lacking iron-related morbidities.[2–6] *Allo-HSCT*, Allogeneic hematopoietic stem cell transplantation; *HLA*, human leukocyte antigen; *TDT*, transfusion-dependent β-thalassemia.

donor sources such as umbilical cord blood also have been used with some success, but because of the limited number of stem cells in each cord blood unit, this is limited to smaller children. Preexisting morbidities such as hepatomegaly, with or without fibrosis, and severe (inadequately treated) iron overload, increase the risk of failure.[336,337]

Stem cell transplantation can fail or be lethal owing to its immunologic complications. The complications related to the procedure are similar to those that would occur in other allogeneic transplants and are related to preparative myeloablative chemotherapy, the risk of infection during the neutropenic period prior to engraftment, the occurrence of graft-versus-host disease (GVHD), and loss of the graft. The overall incidence of acute GVHD is 17% to 32% depending on the prophylaxis regimen, and the incidence of chronic GVHD is 27% in patients receiving hematopoietic stem cells from an HLA-matched parent or sibling.[341] In addition, side effects, such as infertility and clonal disease from the conditioning chemotherapy, are sometimes deterrents for patients who are seeking a curative approach.

Novel Therapeutic Approaches

Major advances in the care of individuals with thalassemia have significantly increased life expectancy in this disease. However, the current paradigm of care remains very cumbersome and has a major impact on quality of life of these individuals and their families. Optimal care requires frequent visits to the hospital for transfusions, monitoring and doctor visits, daily intake of medications with attendant side effects, some persistent symptoms of chronic anemia even in transfused patients, and the potential for complications related to the treatment regimen. Individuals lose days at work or in school, have reduced family time, and suffer an ongoing drain on financial resources, not to mention the psychosocial impairment of dealing with a chronic disease. Knowing the inexorable course of the disease, parents and patients with the option of cure by HSCT most often avail of it, despite the known risk of complications described. However, many individuals do not have a matched related donor, and are thus left to manage a complex disease. Individuals with more severe thalassemia intermedia, while on a less demanding regimen, must cope with anemia and the complications related to IE. Therefore, there remains a significant unmet need for individuals with thalassemia—the need for therapies that would affect the course and provide relief from the burden of the disease and its management.

Over the past decade, major advances have been made thanks to technological developments which have opened a new era of targeted agents and gene therapy. Several approaches have been advanced, and many of these are already in advanced stages of clinical trials with impending regulatory approval for clinical application. These are summarized in Fig. 41.19). A brief description of each emerging modality follows.

Augmentation of fetal Hb production. In the absence of adequate β-globin production, if the excess α globin chains could be bound with γ globin, to produce HbF, this could increase the Hb level and ameliorate IE to a variable extent, thus modifying the pathophysiologic course of the disease.[342] Hypomethylation of the γ-globin genes can be induced by the drug 5-azacytidine; indeed, short-term administration of this drug produced the predicted effect in vivo.[343–345] Despite much subsequent experimental work, it remains unclear whether the effect was attributable to direct stimulation of fetal genes by demethylation or to recruitment and accelerated differentiation of primitive burst-forming unit-erythroid progenitor cells, which have greater potential to produce HbF.[346–348] Hydroxyurea has an effect on burst-forming unit-erythroid similar to that of 5-azacytidine and is a safer drug for long-term use.[347,349] Short-term as well as longer trials with hydroxyurea have been reported in a number of patients with thalassemia.[350–357] HbF levels frequently increased without a proportionate increase in total Hb level. A small improvement in total Hb level occurred in some patients with thalassemia intermedia but usually does not exceed 1 to 2 g/dL.[354,355] Most transfusion-dependent patients have shown no clinical benefit to hydroxyurea. Other approaches using butyrate analogues[358] also did not show sustained positive results. These pharmacological approaches have more or less been abandoned. Two novel strategies are now being employed to augment fetal Hb production.

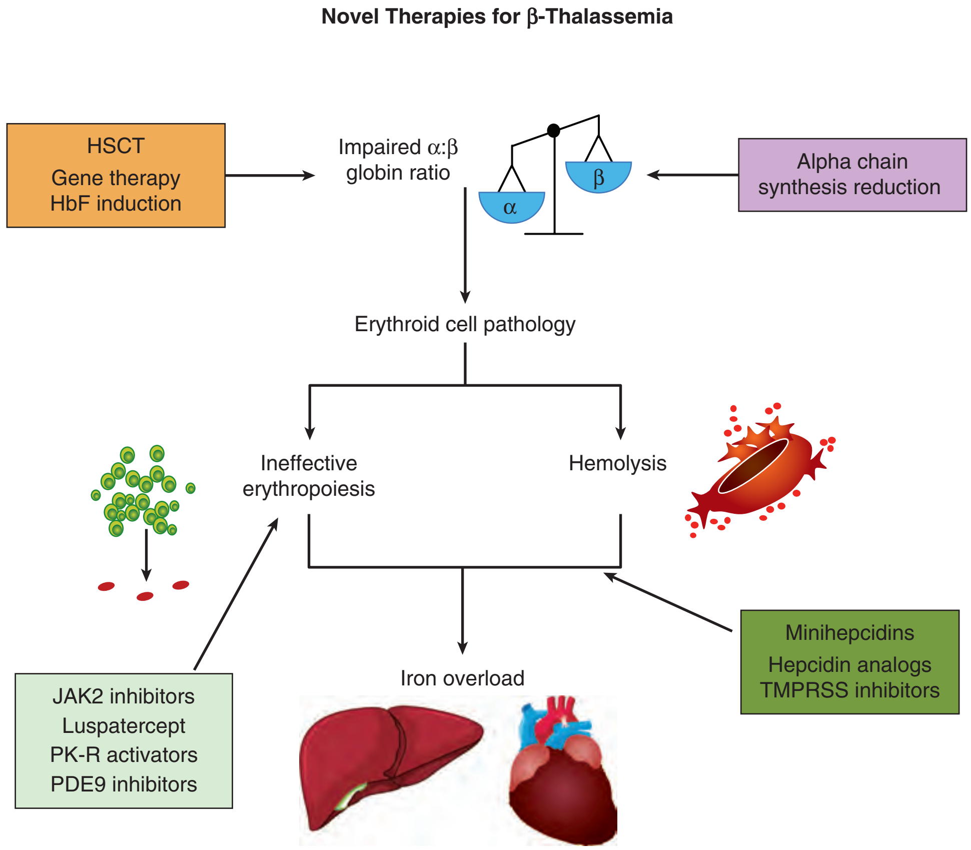

Figure 41.19 VARIED APPROACHES FOR NOVEL THERAPEUTIC INTERVENTIONS IN THE TREATMENT OF β-THALASSEMIA. *(Modified from Cappellini MD, Motta I. New therapeutic targets in transfusion-dependent and -independent thalassemia. Hematology Am Soc Hematol Educ Program. 2017[1]:278–283.)*

(i) Inhibition of phosphodiesterase 9 (PDE9) by the compound IMR-687. This has been shown in thalassemia mouse models to increase cGMP by inhibiting conversion of cGMP to GMP by PDE9. Early studies in patients with sickle cell disease showed increases in HbF and proportion of F cells. A clinical trial in thalassemia is in progress.[359]

(ii) Blocking the repression of γ-globin gene expression by BCL11A. Novel approaches based on our better understanding of the silencing of γ-globin gene expression by BCL11A[360] have led to the development of gene-editing strategies. BCL11A is a zinc-finger transcriptional repressor active in erythroid cells and in other hematopoietic lineages.[361] Several studies indicate that BCL11A silences γ-globin.[361–363] BCL11A does not bind the γ-globin promoter directly. Rather, it binds motifs in the LCR and different intergenic regions in the globin locus that were previously tied with γ-globin repression.[361,364–367] Knock down of BCL11A expression results in the reactivation of HbF expression.[368] Gene therapy or gene-editing techniques are used to modify the patient's own hematopoietic stem cells The corrected stem cells are transferred via an autologous hematopoietic stem cell transplant (Fig. 41.20). The patient's stem cells are collected by pheresis after mobilization from the marrow, purified, and sent to a central facility, where the cells undergo genetic modification. After myeloablative conditioning, the modified stem cells are reinfused. Once these engraft successfully, and begin to produce γ-globin, hemoglobin F containing 2 α-globin chains and 2 γ-globin chains is produced. Success depends on successful editing and engraftment of adequate numbers of stem cells. several approaches have been used and are in clinical trials: (a) introduction of a viral vector encoding an inhibitory RNA (RNAi) that interferes with the ability of BCL11a to interact with its cognate enhance sequence motifs; (b) targeting protein-DNA interactions using either transcription activator-like effector nucleases (TALENS) or zinc finger nucleases,[369] and (c) targeting RNA-DNA interactions using CRISPR-Cas-9.[370] Early results from this trial in 5 patients with thalassemia have shown successful engraftment of the edited stem cells with excellent expression of HbF, suggesting that this strategy is feasible and could result in durable continued expression of γ-globin, and thus production of HbF.

Targeted therapies aimed at ameliorating IE. Several molecules have been/are being developed with the aim of reducing IE and thus not only improving red cell production and reducing anemia, but also possibly preventing progressive bone disease as a result.[371] These include:

(i) Luspatercept: This is a recombinant fusion protein containing a modified extracellular domain of ActRIIB, which binds GDF11 and other TGF-β superfamily ligands, inhibits Smad2/3 signaling, and promotes RBC differentiation/maturation. As a result more proliferating erythroid precursors are able to mature, reducing intramedullary apoptosis, and ameliorating IE. Early studies in normal human volunteers showed a dose-dependent increase in Hb levels, and a good tolerability profile.[372] Phase II studies confirmed that IE was improved in patients with both TDT and NTDT, with clinically meaningful reductions in transfusion requirements.[373] The phase III 48-week BELIEVE study in adults with TDT met all of its primary and secondary endpoints for significant reduction in transfusion requirements by 33% to 50% compared with baseline. An extension phase is ongoing and will inform as to the durability of this therapy, which is now approved for clinical use.[374]

(ii) Ruxolitinib: This JAK2 inhibitor was developed based on the demonstration that JAK2 played a role mediating IE and its inhibition in the mouse model improved effective erythropoiesis and reduced splenomegaly.[375] However, the phase 2a study in individuals with TDT did not show a reduction in transfusion requirement, though there was significant reduction in spleen size.[376] No further studies using this agent are planned.

(iii) Hepcidin analogs: A clearer understanding of IE in thalassemia and the interaction between erythropoiesis and hepcidin via ERFE led to the use of hepcidin analogs in the mouse model of thalassemia.[377] Treated mice showed a reduction in spleen size and improvement of anemia.[378] A potential additional benefit would be to directly inhibit iron absorption and slow the development of iron overload. Further, increasing hepcidin would sequester iron in stores, prevent release, and therefore reduce iron exposure of the heart and endocrine organs. Clinical trials of these analogs have been initiated in humans, looking for reductions in transfusion requirement as the endpoint.[379] In a different study, patients with thalassemia and transfusional iron overload were given hepcidin to study its effect on myocardial iron.[380] However, this trial was terminated after the interim analysis did not show any beneficial effect.

(iv) AG-348 (Mitapivat): Improving aerobic glycolysis and reducing oxidative stress in developing erythroid precursors could ameliorate apoptosis and IE and increase production of red cells. Further, these red cells may also have a longer lifespan. Mitapivat is an oral, small molecule allosteric activator of wild-type and a variety of mutated pyruvate kinase-R (PKR) enzymes. In non-transfusion-dependent individuals with β thalassemia intermedia and HbH disease, early short-term phase II data show an increase in Hb levels and a reduction in markers of hemolysis. This agent is in clinical trials in NTD patients,[381] and trials in TDT are planned.

(v) FT-4202 is another pyruvate kinase activator which has shown benefit in sickle cell disease, with the same mechanism of action postulated as AG348. Clinical trials in thalassemia are also planned.

Correction of the defective globin gene. The most advanced and exciting curative strategy for the thalassemias is aimed at correcting the defective gene. The only reliable conventional curative treatment, allogeneic HSCT from a matched related donor, is available to a limited proportion of patients with such a donor. A gene therapy approach, being autologous, greatly expands the pool of patients who could be cured.[382–387]

This is done either by adding a new copy of the gene or possibly by correcting the defective gene through CRISPR/Cas-9 splicing. Gene addition strategies are in fairly advanced stages of clinical trials. The first successful gene therapy for β-thalassemia was reported in 2010, when a patient with HbE/β^0 thalassemia was cured using a lentiviral vector.[388] The corrected stem cells are transferred via an autologous hematopoietic stem cell transplant (see Fig. 41.20). The patient's stem cells are collected by pheresis after mobilization from the marrow, purified, and taken to the gene transfer facility. A functional copy of the β-globin gene (or possibly γ-globin gene) is introduced into the stem cells via transfection by a lentiviral vector. After myeloablative conditioning, the modified stem cells are reinfused. Once these engraft successfully, and begin to produce β-globin, hemoglobin A, containing 2 α-globin chains and 2 β-globin (normal or modified) chains is produced. The efficacy of the process depends on successful transfection of the stem cells in adequate numbers, the engraftment of these cells, and the maintenance of a high vector copy number (VCN) per cell to ensure adequate β-globin production. An added benefit of this approach is the virtual absence of graft-versus-host disease in the autologous setting.

Two vectors are currently in trials:

(i) BB305 vector: This vector (Fig. 41.21) encodes a β-globin gene which produces a β-globin chain with a single amino acid substitution—T87Q—resulting in the production of HbAT87Q, thus allowing easy measurement of the gene product as different from endogenous HbA production. Early clinical trials using this vector demonstrated proof of principle early, and a proportion of patients with both non-β^0/β^0 (and β^0/β^0 genotypes[389,390] showed robust production of the HbAT87Q, with transfusion independence, more in the non-β^0/β^0 patients. Patients who did not respond as well still experienced a reduction in transfusion requirements. Single agent busulfan myeloablative conditioning was used. The therapy was safe, with no deaths or graft failures during the trial, and all complications were expected and similar to those seen from myeloablative conditioning in allogeneic HSCT, including neutropenic fevers, mucositis, and veno-occlusive disease. No graft-versus-host disease was noted. Furthermore, vector integration was polyclonal, and there was no vector-mediated replication-competent lentivirus detected, thus providing reassurance that there was a very low risk for insertional mutagenesis. In addition, there was stable transfection, with a VCN in the 0.6 to 0.7 copies per cell, and stable production of HbAT87Q in most patients.[391] These patients have now been followed for approximately 5 years, and the graft appears durable.

Clinical trials using the same vector but manufactured with a refined process are currently underway in non-β^0/β^0 patients[392] and β^0/β^0 patients,[393] and preliminary results show improved VCNs in the 2 to 3 range, with a correspondingly greater production of

HbAT87Q and thus a greater proportion of patients with transfusion independence. These data are being updated regularly, and so far, results are very promising, with success rates similar to those following allogeneic HSCT from a matched related donor.

(ii) GLOBE vector: Also a lentiviral vector, this contained a normal human β-globin gene with no modifications. Other differences from the BB305 trials were the use of thiotepa and treosulfan for myeloablative conditioning, and the introduction of the modified cells directly into the BM to avoid passage through, and possible clearance by the spleen. Though still early, the preliminary results from this phase I/II trial[394] have been positive.[395]

ALPHA-THALASSEMIA SYNDROMES

The α-thalassemias also occur widely throughout the world, including Africa, the Mediterranean countries, the Middle East, and Southeast Asia.[2,396,397]

As in β-thalassemia, there is some heterogeneity in presentation of the more severe forms of α thalassemia, but much less so. Genotype-phenotype correlation is consistent, and most of these individuals do not have a significant degree of IE, making them somewhat different than individuals with β-thalassemia. Since each individual normally has 2 α-globin genes on each chromosome 16, there are 4 genotypes of α-thalassemia, with 3, 2, 1, or no functioning α-globin genes.

The α-thalassemias are more difficult to diagnose because the characteristic elevations in HbA2 or HbF seen in β-thalassemia do not occur, precluding the use of hemoglobin fractionation for diagnosis. However, the gene deletions responsible for the most common varieties are readily detectable by molecular biology methods.[398]

Genetics

The four classic α-thalassemia syndromes are α^+-thalassemia trait, in which one of the four α-globin genes is non-functional; α^0-thalassemia trait, with two dysfunctional genes; HbH disease, with three affected genes; and hydrops fetalis with Hb Bart, in which all four genes are defective. In general, partial deletions are more deleterious and create a more severe phenotype than complete deletions.[399] In the older literature, α^0- and α^+-thalassemia are referred to as α-thalassemia-1 and α-thalassemia-2, respectively. Non-function of α-globin genes is usually deletional (Fig. 41.22). At the molecular level, α^+-thalassemia has been found to be associated with two common gene deletions resulting from different nonhomologous crossing-over events between the two linked α-globin genes: a 3.7-kb rightward deletion ($-\alpha^{3.7}$) resulting in a fused α2α1-globin gene and a 4.2-kb leftward deletion ($-\alpha^{4.2}$) resulting in loss of the 5′ (α2) gene.[400–402] One or two α gene deletions occur at a high frequency throughout West Africa, the Mediterranean, the Middle East, and Southeast Asia. In the United States, about 30% of Americans of African descent carry these defects. In some parts of Papua New Guinea up to 80% of the population are carriers. When two genes are deleted, this may occur in the *cis* or *trans* configuration and has implications for offspring should both parents have α-thalassemia trait. α^+-thalassemia trait inherited in *trans* configuration is very common in individuals of African or Middle Eastern ancestry, and since *cis* α^0-thalassemia deletion is rare in these individuals, HbH disease is rarely encountered, and hydrops fetalis has not yet been reported in individuals of African ethnicity.[403,404] α^0-thalassemia trait inherited in *cis* configuration is common in individuals of Asian ancestry, and hence HbH and hydrops are more commonly seen in these populations. α^0-thalassemia trait inherited in *cis* configuration is also found in Mediterranean populations, but less frequently than in Asians.

Nondeletional forms of α-thalassemia, which account for 15% to 20% of patients, arise from mutations similar to those described for β-thalassemia.[400,401] Fig. 41.23 illustrates the different α-thalassemia mutations and phenotypes. Structurally abnormal hemoglobins have also been associated with α-thalassemia. The Quong Sze α-globin chain ($\alpha^{125\text{Leu}\rightarrow\text{Pro}}$) is exceedingly labile and is destroyed so rapidly after its synthesis that no Hb tetramers containing the mutant α chain can be formed.[405] α^+-thalassemias also exhibit epistasis with haptoglobin variants that alters patterns in malaria protection.[406] How common the nondeletion forms of α^+-thalassemia are in any particular populations is uncertain, but they have been reported quite frequently in some of the Mediterranean island populations and in the Middle Eastern and Southeast Asian populations. The α-chain termination mutants, such as Hb Constant Spring, seem to be particularly common in Southeast Asia. Approximately 4% of the population in Thailand are carriers.

Previously, the diagnosis of α-thalassemia trait was usually one of exclusion, with a microcytic anemia and normal iron studies and Hb Fractionation. However, with the ready availability of globin gene analysis in the developed world, the diagnosis of α-thalassemia is now easier to make conclusively. These tests are also used for prenatal diagnosis of HbH or α-thalassemia major.

Molecular Pathology and Pathophysiology

As there is a relative excess of non-β-globins in β-thalassemia, there is an excess of non–α-chain production in the α-thalassemias, but the consequences are quite different. Alpha globin chains are required for HbF and HbA production, therefore, defective α-chain production is manifest in both fetal and adult life. In the fetus, excess γ-chain production results in formation of γ4 homotetramers or Hb Bart, while in the adult, excess of β chains forms β4 homotetramers or HbH. Hb Bart and HbH do not precipitate to any significant degree in the marrow, and therefore the α-thalassemias are not characterized by severe IE despite marked globin-chain imbalance in the severe α-thalassemias.[407] The erythroid marrow is more effective, and marrow

hyperplasia and EMH are not as significant. However, β4 tetramers precipitate as red cells age, with the formation of inclusion bodies which leads to a shortened survival of red cells from their damage in the microvasculature of the spleen. Therefore, anemia of the more severe forms of α-thalassemia in the adult results from hemolysis more than IE. Hb Bart is more stable than HbH and does not form large inclusions. Also, both Hb Bart and HbH show no heme-heme interaction and have almost hyperbolic oxygen dissociation curves with very high oxygen affinities. They are, therefore, not able to effectively release oxygen at physiologic tissue tensions making them very poor oxygen carriers, which exacerbates hypoxia from the anemia, with potentially severe consequences. Infants with high levels of Hb Bart in α-thalassemia major have severe intrauterine hypoxia, which is probably responsible for the enormously hypertrophied placentas, the severe erythroblastosis, the gross hydropic state of the fetus as a result of increased capillary permeability and possibly for the associated developmental abnormalities that occur with the severe forms of intrauterine α-thalassemia.

The two α-globin genes on each chromosome, α1 and α2, do not function identically. Studies of newborns from the archipelago of Vanuatu in the Southwest Pacific and from Papua New Guinea indicate that homozygotes for the rightward $-\alpha^{3.7III}$ deletion (where only a fused α*2*α1-globin gene, mostly of the α2 type, remains) have lower Hb Bart levels (3.5% ± 0.8%) than those of infants homozygous for the leftward $-\alpha^{4.2}$ deletion (in whom only the α1-globin gene remains) (6.0% ± 1.4%). These results suggest that the 5′ α2-globin gene has a higher output than the 3′ α1-globin gene, a conclusion supported by direct measurement of α2/α1 mRNA ratios.[408,409]

Clinical Manifestations and Diagnosis

Silent Carrier (α^+-Thalassemia Trait)

Individuals with α^+-thalassemia trait are typically completely asymptomatic and have no consistent hematologic manifestations. The Hb level is normal, and the RBCs are usually not microcytic. HbA2 and HbF are normal. During the newborn period, small amounts (≤3%) of Hb Bart (γ_4) may be seen. This condition is most often recognized when an apparently normal individual becomes the parent of a child with HbH disease after mating with a person with α^0-thalassemia trait in *cis* form. The mild excess of β-globin chains is probably removed in erythroblasts by proteolysis.[410] α^+-thalassemia is particularly common in Melanesia, as well as in Southeast Asia and in African Americans, reaching a prevalence of more than 80% in north coastal Papua New Guinea.

The level of α-globin gene expression differs in the two conditions, as discussed in the following section.

α^0-Thalassemia Trait (α-Thalassemia Trait)

These individuals typically present with a mild microcytic anemia, similar to those with β-thalassemia trait. They are usually asymptomatic and have no other clinical manifestations of thalassemia. Levels of HbA2 in the low to low-normal range (1.5% to 2.5%) and β/α synthetic ratios averaging 1.4:1 characterize α^0-thalassemia trait. During the perinatal period, elevated amounts of Hb Bart are noted (3% to 8%). Microcytosis is present in cord blood erythrocytes. The degree of anemia and amount of Hb Bart may be related to whether the α1 or α2 genes are deleted.

HbH is not detected in hemolysates of peripheral RBCs, probably because of rapid proteolysis of HbH or free β-globin chains. However, approximately 1% of erythroblasts and BM reticulocytes have inclusions. When an α-thalassemia gene occurs in persons who are also heterozygous for α-globin chain variant Hbs, such as HbS, HbC, or HbE, the proportion of the abnormal Hb is lower than that seen in simple heterozygotes.[411] The lower level of the abnormal Hb is attributable to posttranslational control because of higher affinity of β^{A} chains for a limited pool of α-globin chains coupled with proteolysis of the uncombined $\beta^{variant}$ chains.[412] In the nondeletion forms of α-thalassemia, there may be an extremely diverse series of phenotypes, with some individuals being more anemic, and having the clinical picture of HbH disease, while others may have only mild hypochromic anemia like the deletional form.

Hemoglobin H Disease

HbH disease is associated with a moderately severe but variable anemia resembling β-thalassemia intermedia, with osseous changes and splenomegaly.[413] It occurs predominantly in Asians and occasionally in persons of European (Mediterranean) descent but is rare in persons of African ancestry. Deletional HbH occurs when three deletional alpha mutations occur. Non-deletional HbH occurs when two deletional alpha mutations occur with an alpha (+) mutation (e.g., Constant Spring). Though all patients have anemia, the degree is variable, based on the expression of the single α-globin gene, and any other potential genetic disease modifiers. The clinical phenotype varies considerably, being considerably milder in some patients and severe enough to cause hydrops fetalis in others.[414,415] While a few may have severe anemia, and require regular or intermittent transfusions, most have a much milder course.[2,416] Some symptoms of the chronic microcytic anemia may be seen, such as fatigue and exercise intolerance, but these are usually not severe. Since HbH is unstable, it precipitates within the circulating RBCs and hemolysis occurs. The higher the proportion of HbH, the more hemolytic the clinical phenotype. Nondeletional HbH genotypes are more likely to have higher percentage HbH, more hemolysis, more splenomegaly, and more advanced disease.[406]

Since the degree of IE in α-thalassemia is mild, splenomegaly is somewhat variable, and the other clinical manifestations of the thalassemia intermedia syndrome, such as bone disease and iron overload are not frequently seen, though adults with deletional HbH may develop some of the same complications as β-thalassemia intermedia, including osteoporosis, cholelithiasis, and iron overload.[417] The degree of deletions in HbH is also relevant to clinical presentation.

Exacerbations of anemia during febrile illnesses are common and are usually characterized by increasing fatigue and jaundice.

HbH can be demonstrated by incubation of blood with supravital oxidizing stains such as 1% brilliant cresyl blue. Multiple small inclusions form in the RBCs. Electrophoresis of a freshly prepared hemolysate at alkaline or neutral pH demonstrates a fast-moving component amounting to 3% to 30% of the total Hb. Concomitant iron deficiency may reduce the amount of HbH in the patient's RBCs.[418] A syndrome of HbH disease associated with mental retardation, other congenital anomalies, and large deletions on chromosome 16 has been noted in several families of European origin.[419,420]

Hydrops Fetalis With Hb Bart

Alpha-thalassemia major (homozygous α^0 thalassemia) is found most commonly in Mediterranean and East Asian (Chinese, Cambodian, Thai, and Filipino) populations because of the higher prevalence of two gene deletions in *cis* configuration, but is rare in African and Middle Eastern populations, where two gene deletions are usually in *trans* configuration. Affected fetuses are usually born prematurely and are either stillborn or die shortly after birth.[2–4,6] Hydropic infants have marked anasarca and massive hepatosplenomegaly. Extreme extramedullary erythropoiesis occurs in response to the profound hypoxia and hemolytic anemia characteristic of this disease. The universal edema characteristic of the hydrops fetalis syndrome is a reflection of severe congestive heart failure and hypoalbuminemia in utero. This is partly a consequence of anemia, but the strikingly abnormal oxygen affinity of the tetrameric Hb Bart is probably the most important determinant of the severe tissue hypoxia. The oxygen dissociation curve of Hb Bart lacks the normal sigmoid form because of noncooperation during oxygen loading and unloading and is markedly shifted to the left. The shift is so great that little oxygen is released under conditions of low oxygen concentration in the tissues.

Infants with this syndrome do not die in an earlier trimester of pregnancy because of the presence of Hb Portland ($\zeta_2\gamma_2$). This Hb does display cooperativity in a manner similar to that of HbF and therefore has a much more favorable oxygen dissociation pattern than that of Hb Bart. A high incidence of toxemia of pregnancy has been described in women carrying severely affected infants, providing an increased rationale for prenatal diagnosis of this condition.

Severe anemia is usually present, with Hb levels of 3 to 10 g/dL. The RBCs are markedly microcytic and hypochromic and include target cells and large numbers of circulating nucleated RBCs. These morphologic abnormalities and a negative Coombs test result exclude hemolytic diseases caused by blood group incompatibility.

Hb electrophoresis reveals predominantly Hb Bart, with a smaller amount of HbH. A minor component identified as Hb Portland ($\zeta_2\gamma_2$) migrating in the position of HbA is also seen. Normal HbA and HbF are totally absent.[421]

Therapy

Fetuses with homozygous α^0-thalassemia usually die in utero because of severe hydrops fetalis and are stillborn. However, some infants have had successful blood exchange transfusion immediately after birth.[422–426] It is also possible to salvage affected fetuses by in utero blood transfusions.[427,428] Limb and urogenital defects are present in a substantial portion of infants with homozygous α^0-thalassemia who are rescued by these measures, and some infants have developmental delay or other neurologic abnormalities. Management after the perinatal period is similar to the management of patients with β-thalassemia major and includes transfusion and chelation therapy as well as the possibility of BMT.[429]

Most patients with HbH disease do not require RBC transfusions. For patients with more severe disease, characterized by lower Hb levels or frequent exacerbations of the anemia, splenectomy can be helpful. Oxidant drugs can accelerate precipitation of HbH and exacerbate hemolysis; they should therefore be avoided. Exchange transfusion can be used to decrease deleterious levels of HbH.

Infants with heterozygous α^0-thalassemia trait lose their Hb Bart during the first few months of life and are left with the hematologic findings of α-thalassemia trait, a mild hypochromic microcytosis that persists throughout life.[2] These individuals do not require any therapy, and the same guidelines are followed for their care as with β-thalassemia trait. Iron supplementation is only necessary if there is true iron deficiency, and routine supplementation to raise the hemoglobin level is futile and should not be done. These individuals should seek genetic counseling when ready for childbearing.

Novel Therapies

Several newer approaches are being studied for α-thalassemia:

A. In order to ameliorate anemia in individuals with HbH disease, AG-348 (Mitapivat) will be entering a phase II/III clinical trial in NTD HbH patients. Mitapivat is an oral, small molecule allosteric activator of wild-type and a variety of mutated PKR enzymes. In non-transfusion-dependent individuals with β-thalassemia intermedia and HbH disease, early short-term phase II data show an increase in Hb levels and a reduction in markers of hemolysis. This agent is in clinical trials in NTD patients.[430]

B. A phase I clinical trial to evaluate the safety of in utero HSCT in fetuses with α-thalassemia major is also underway.[431] Maternal BM would be infused at the time of the in utero red cell transfusion. The goal is to take advantage of the maternal-fetal tolerance that exists during pregnancy, thus no conditioning chemotherapy would be required.

De Novo and Acquired Forms of α-Thalassemia

Two distinct α-thalassemia syndromes have been described that are attributable to acquired or de novo mutations: (1) α-thalassemia associated with mental retardation and (2) HbH disease associated with MDS.

α-Thalassemia Associated With Mental Retardation

Alpha-thalassemia or HbH disease can occur as a de novo abnormality in a rare disorder called the α-thalassemia with mental retardation syndrome (ATR).[419,420] In this disorder, affected patients have mental retardation and a number of other developmental abnormalities in association with α-thalassemia trait or HbH disease that is inherited in a nontraditional manner. Two distinct types of the ATR syndrome have been identified. In some cases, there is the de novo appearance of large (2000 kb or so) deletions involving the entire α-globin gene cluster and adjacent DNA at the tip of chromosome 16, the so-called ATR-16 syndrome. In some of these patients, the deletion produces detectable cytogenetic abnormalities of chromosome 16, indicating that a very large segment of the chromosome is deleted, sometimes because of unbalanced chromosomal translocations involving the telomeres of the affected chromosomes. In some cases, one parent is heterozygous for α^+-thalassemia by various criteria and the other parent is completely normal; in such cases, the child has HbH disease (- -/- α). In other cases, both parents are normal and the affected child has the hematologic phenotype of heterozygous α^0-thalassemia (- -/αα) without HbH disease. In this form of ATR, the clinical findings, such as the degree of mental retardation and associated congenital abnormalities, are variable.

The second type of ATR syndrome is not associated with detectable deletions of the α-globin gene complex. The molecular basis of the disorder consists of mutations of a gene on the X chromosome, and the condition has been called the alpha-thalassemia/mental retardation, X-linked (ATR-X) syndrome.[432] In contrast to patients with the ATR-16 syndrome who have a varied phenotype of developmental abnormalities, patients with the ATR-X syndrome have a more uniform or consistent phenotype, particularly severe mental retardation (with IQs of 50 to 70) and a characteristic dysmorphic facial appearance.[420]

The affected gene in this syndrome encodes a *trans*-acting factor, called ATR-X, that is thought to influence the expression of the α-globin genes as well as that of other genes.[433,434] The structure of this large (280 kDa) DNA-binding protein is complex and contains two major functional domains: an *N*-terminal cysteine-rich zinc finger–containing domain, called the ADD domain, that has structural features similar to those of DNA methyl transferases, and a C-terminal helicase/ATPase domain. The majority of the mutations associated with the ATR-X syndrome are located in the ADD domain or the helicase domain. The ATRX protein is widely expressed in many different tissues and its intracellular localization is within three different nuclear subcompartments: heterochromatin, ribosomal DNA arrays, and promyelocytic leukemia (PML) bodies. It has been shown to interact with other proteins such as the heterochromatin-associated protein HP1 and Daxx, one of the proteins localized in PML bodies. The prevailing opinion is that the ATRX protein is part of a large chromatin-remodeling complex of the SWI2/SNF2 family. It also has ATPase activity and has translocase activity, that is, it can move along DNA as a "molecular motor." The precise mechanism(s) by which ATRX influences the expression of α-globin (and other) genes remains unknown.

Acquired HbH Disease Associated With Myelodysplastic Syndrome (ATMDS)

HbH disease has occasionally been observed to develop during the course of different types of MDS and more rarely in patients with other hematologic malignancies.[435] The disorder usually affects men over the age of 60 years. The degree of imbalance of globin chain synthesis and of α-globin mRNA deficiency in erythroid cells of affected patients is greater than that observed in the hereditary type of HbH disease. It is conceivable that erythroid cells of the abnormal clone synthesize no α-globin chains at all and that the expression of all four α-globin genes is suppressed or silenced,[436] but this phenomenon is difficult to quantify as long as some normal erythroid cells are being produced.

Cytogenetic, gene mapping, gene sequencing, and gene or chromosome transfer studies failed to detect any deletion or mutation in the α-globin gene cluster or functional abnormality of α-globin gene of affected patients. The results of all of these prior studies suggested that the defect responsible for this disorder probably involved the abnormal expression or function of a *trans*-acting factor capable of influencing α-globin gene expression and, indeed, such a factor was recently identified. The discovery of the factor responsible for HbH disease in MDS results from cDNA microarray analysis of RNA isolated from granulocytes of an affected patient. One of the genes that was found to be markedly underexpressed, compared with results obtained with RNA of normal granulocytes, was the *ATRX* gene,[437] the same gene that is mutated in the α-thalassemia with mental retardation syndrome of the ATR-X type. Sequence analysis of the *ATRX* gene in the DNA of blood cells of affected individuals has identified a number of different mutations. It is noteworthy that the mutations of the *ATRX* gene associated with acquired HbH disease associated with MDS (ATMDS) occur in the same regions of the gene as the mutations associated with the ATR-X syndrome, that is, in the ADD or helicase domains. In fact, some of the *ATRX* gene mutations identified in ATMDS are identical or similar in expected functional consequences to various mutations found in the ATR-X syndrome.

The hematologic features in the syndrome are characterized by the presence of a dimorphic RBC population on blood smear, one of which is hypochromic, microcytic, and poikilocytic. Incubation of the blood with the supravital stain brilliant cresyl blue results in the detection of typical HbH inclusions. Hb electrophoresis or HPLC detects the presence of HbH, usually in greater quantities than that typically observed in inherited HbH disease. In typical MDS, the MCV of the erythrocytes is normal or elevated, frequently higher than 100 fL. However, in ATMDS, the MCV and MCH are low: MCV usually less than 80 fL and MCH usually less than 26 pg.[435] The amount of HbH usually remains stable but may actually decrease during the course of the disease and no longer persists after transformation of MDS to acute leukemia. This finding suggests that the HbH-producing clone does not have a selective survival or growth advantage.

The hematologic phenotype, as reflected by the amount of HbH present in blood, of ATMDS is much more severe than that of the ATR-X syndrome.[433] Some of this difference in severity may be because of the nature of the ATMDS mutations, some of which are null mutations that are likely to be lethal when present in germline DNA of ATR-X embryos. However, the difference in severity is also observed in the case of mutations found in both syndromes that are identical or similar in expected functional consequences. This finding suggests that additional abnormalities in gene expression in ATMDS contribute to the severity of the deficit in α-globin gene expression observed in this syndrome. Perhaps the responsible defective cofactor(s) is one or more of the proteins that interact with the ATRX protein to produce a fully functional macromolecular complex that can act as a transcriptional cofactor or that can influence the epigenetic control of α-globin gene expression.

THALASSEMIC STRUCTURAL VARIANTS

Certain structural Hb variants are characterized by the presence of a biosynthetic defect as well as abnormal structure.[7] Thalassemic hemoglobinopathies are unusual forms of thalassemia caused by such structural variants.

Hemoglobin Lepore

Hb Lepore (α2δβ) is the prototype of a group of hemoglobinopathies characterized by fused globin chains.[2–4,6] The chains begin with a normal δ-chain sequence at their N-terminus and end with the normal β-chain sequence at their C-terminus. These hemoglobinopathies arise by unequal or nonhomologous crossover or recombination events that fuse the proximal end of one gene with the distal end of a closely linked structurally homologous gene (Fig. 41.24). During meiosis, mispairing and crossover of the highly homologous δ- and β-globin genes can occur, resulting in a Lepore chromosome, which contains (in addition to γ-globin genes) only the fused δβ gene, and an anti-Lepore chromosome, which contains the reciprocal fusion product (δβ), as well as intact δ- and β-globin genes.[2]

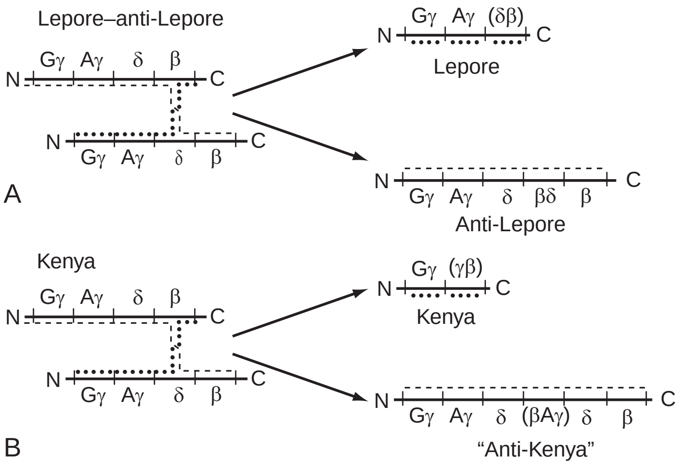

Figure 41.24 GENETIC ORIGINS OF HEMOGLOBIN (HB) LEPORE, ANTI-LEPORE HB, AND HB KENYA. *(Adapted from Benz EJ Jr. The hemoglobinopathies. In: Kelly WN, DeVita VT, eds. Textbook of Internal Medicine. Philadelphia: JB Lippincott; 1988:1423.)*

Lepore globin is synthesized in low amounts, presumably because it is under the control of the δ-globin gene promoter, which normally sustains transcription at only 2.5% the level of the β-globin gene.[438] Patients with Hb Lepore have the phenotype of β-thalassemia, distinguished by the added presence of 5% to 15% Hb Lepore. In contrast, the anti-Lepore globin (Miyada) is not associated with a β-thalassemia phenotype because of the presence of an intact and functionally normal β-globin gene on the same chromosome.

An analogous but rare variant, Hb Kenya (α2[Aγβ]2), arises from nonhomologous crossing over between the $^{A}\gamma$- and β-globin genes[439] and is associated with the phenotype of Gγ hereditary persistence of fetal Hb. A DNA sequence approximately 600 bases downstream from the β-globin gene acts as a strong enhancer, promoting the erythroid-specific expression of the β-globin genes in adult cells.[3,4,18] The fused $^{A}\gamma\beta$ gene as well as the linked upstream $^{G}\gamma$ gene are believed to come under the influence of the enhancer because of its abnormal proximity and thus are expressed at high levels in adult life.

Hemoglobin E

HbE ($\alpha_2\beta_2^{26Glu\rightarrow Lys}$) is a common variant (15% to 30% of the population) in Cambodia, Thailand, parts of China, and Vietnam. HbE is very mildly unstable, but this instability does not significantly alter the life span of RBCs. HbE trait resembles very mild β-thalassemia trait. Homozygotes exhibit more microcytosis but are still asymptomatic.[440] Compound heterozygotes for HbE and a β-thalassemia gene (HbE-β-thalassemia) resemble patients with β-thalassemia intermedia or β-thalassemia major. However, some problems such as infection and pulmonary hypertension may occur more commonly in HbE-β-thalassemia than in homozygous β-thalassemia.[441]

The only nucleotide sequence abnormality found in the β^E-gene is a base change in codon 26 that causes the amino acid substitution where glutamic acid is replaced by lysine. This mutation, which occurs in a potential cryptic RNA splice region, alters the consensus sequence surrounding a potential GT donor splice site and thus activates the cryptic site. Alternative splicing at this position occurs approximately 40% to 50% of the time, generating a structurally abnormal globin mRNA that cannot be translated appropriately.[442] The other mRNA precursors are spliced at the normal site, generating functionally normal mRNA, which is translated into β^E-globin because the mature mRNA retains the base change that encodes lysine at codon 26.

Hemoglobin Constant Spring

Hb Constant Spring (see Fig. 41.22) is an elongated α-globin variant resulting from a mutation that alters the normal translation termination codon.[443] Polyribosomes read through the usual translation stop site and incorporate an additional 31 amino acids until another in-phase termination codon is reached within the 3′ untranslated sequence. The amount of α^{cs} mRNA is markedly reduced, and α^{cs}-globin is synthesized in only minute amounts.[402,444] Six possible mutations of the normal translation termination codon (UAA) in α-globin mRNA could result in the generation of a "sense" codon.[445] Of these, five variants have been identified, each having a markedly underproduced abnormal variant, indicating that disruption of normal translation termination is in some way associated with abnormal mRNA accumulation, presumably because of instability of the mRNA.[402] The output of α-globin from the α^{cs} allele is only approximately 1% of normal, and the gene is thus rendered α-thalassemic. The α^{cs} allele has been identified only on chromosomes containing a *cis*-linked functionally normal α-globin gene.[2–4,6] Thus, α^{+}-thalassemia trait (α -/$\alpha^{cs}\alpha$) and HbH disease–(--/$\alpha^{cs}\alpha$) associated with Hb Constant Spring are common, but hydrops fetalis caused by four abnormal α-globin genes cannot occur in association with this variant. Homozygosity for the variant is associated with a relatively mild form of HbH disease.[2]

EXTRAORDINARILY UNSTABLE HEMOGLOBINS

Rare cases of α-thalassemia (e.g., Hb Quong Sze)[405] and β-thalassemia (e.g., Hb Indianapolis, recently renamed Hb Terre Haute)[446,447] arise from mutations that produce extremely labile globin chains. The chains fail to pair with the complementary chain, or they precipitate and are degraded so rapidly that they never form tetramers. These posttranslational lesions have the same pathophysiologic effects on Hb biogenesis as reduction of globin mRNA production or function. Another group of β-globin chain variants, usually caused by mutations in exon 3 of the β-globin gene, are associated with inclusion body formation and a phenotype of dominant β-thalassemia intermedia.[16,17,448]

CHAPTER 42

PATHOBIOLOGY OF SICKLE CELL DISEASE

Robert P. Hebbel and Gregory M. Vercellotti

Since it was recognized as the "first molecular disease," sickle cell anemia (HbSS) caused by homozygosity for the mutant sickle beta-globin gene has provided the classic paradigm for single-gene disorders. Predominant clinical features include hemolytic anemia, episodic painful vasoocclusive events, an inflammatory vasculopathy, chronic organ deterioration, and a foreshortened life span. The genesis of clinical HbSS is complicated, and an understanding of its pathophysiology integrates concepts from multiple scientific disciplines, includes contributions from the red blood cell (RBC) membrane and the vascular wall endothelium, and recognizes the likely participation of multiple genetic influences. This chapter addresses the fundamental pathophysiology that underlies the sickle cell disease syndromes described in Chapter 43.

EARLY YEARS OF SICKLE CELL DISEASE RESEARCH

Sickle disease syndromes were known in folk medicine for centuries in parts of Africa, but the eponymous RBC was first reported in the medical literature in 1910 when Herrick described a young Grenadian man with recurrent pain, anemia, and sickle-shaped red corpuscles in the blood (Fig. 42.1). In 1940, Ham and Castle presciently postulated that sickle disease pathophysiology resulted from a "vicious cycle" involving mutually promotive erythrostasis and RBC sickling with adverse viscosity changes. In 1949, Neel validated the Mendelian inheritance of HbSS, and Pauling demonstrated the presence of an abnormal hemoglobin (Hb) in patients and carriers. This was followed by observation of the poor solubility of deoxygenated sickle Hb (HbS) and the reversible sol-gel transformation of HbS solutions. In 1957, Ingram identified the underlying amino acid substitution. Thereafter, increasingly detailed investigations began to reveal the striking complexities of sickle cell disease pathobiology.

GENETIC CONSIDERATIONS

Molecular Context

The sickle mutation in the *HBB* gene is a GAG→GTG conversion that creates a $\beta^{6\text{Glu}\rightarrow\text{Val}}$ substitution and thereby forms β^S globin chains. Genes for other β-globin variants are allelic to the β^S gene and have a codominant impact. Examples include genes for the normal β chain (β^A), other β mutants (e.g., β^C, β°, or β^+ thalassemia), and deletional hereditary persistence of fetal Hb (HPFH). Compound heterozygosity for β^S and each one of these results in well-defined clinical syndromes, such as HbAS (sickle trait), HbSC disease, HbS–β-thalassemia, and HbS-HPFH. Eight percent of African Americans have a β^S gene, 3% have β^C, 1.5% have β-thalassemia, and 0.1% have HPFH. Among African Americans, about 1 in 600 births results in the homozygous state, HbSS, and about 1 in 400 results in some form of sickle cell disease, which additionally includes the compound heterozygous variants other than HbAS. Worldwide, about 78% of HbSS births now occur in sub-Saharan Africa, 14% in India, 4% in the Americans, 3% in the Eastern Mediterranean, and 1% in Europe.

The *HBB* gene resides in a β-like gene cluster within which are various non-exonic polymorphic sites. Different combinations of these define discrete β-locus backgrounds, referred to as the Senegal, Benin, Bantu, Cameroon, and Arab-India haplotypes. Each refers to an ethnographic region in which the sickle mutation arose and achieved high gene frequency, typically peaking at 0.15 to 0.18. In most cases, the sickle gene resides on one of these five major haplotypes. Recent DNA sequence analysis of these haplotypes has suggested that, in fact, the sickle allele arose just once about 7300 years ago in central Africa and spread to these 5 haplotypes as the result of migration and continued selective pressure from malaria.

Origin, Selection, and Dispersion of the Sickle Gene

The residence of both β^A and β^S alleles on the distinct regional β cluster haplotypes suggests that the sickle mutation was selected for independently in the five regions. The β^C mutation arose only once. Historical and biological data argue that the frequency of the β^S gene greatly expanded in South Asia about 4000 years ago and in Africa about 3000 years ago, following the introduction of iron tools in each case. That led to the adoption of an agricultural system that promoted both increased human habitation density and favorable breeding conditions for the *Anopheles* mosquito, which in turn enabled the development of endemic *Plasmodium falciparum* malaria. In this context, high fixed β^S gene frequencies were reached because of a balanced polymorphism, such that heterozygotes (HbAS) have an adaptive advantage over either homozygote. Thus, the Old World geographic distributions of the sickle gene and historical endemic malaria are notably concordant, suggesting that the sickle gene represents "a biologic solution to a cultural problem."

In hyperendemic areas, *falciparum* malaria uniformly infects the young and is the primary cause of death for children with HbSS. However, those with HbAS are less likely to develop severe malaria, a protective effect appearing early in childhood and possibly increasingly until age 10. At the level of the RBC, this protection reflects steps after the initial parasite invasion. One proposed mechanism links protection to the instability of HbS, immune status, and splenic function. That is, infection of HbAS RBCs with *P. falciparum* leads sequentially to augmented Hb denaturation, clustering of membrane protein band 3, attraction of band 3 autoantibody, complement binding, and enhanced erythrophagocytosis even of the early ring forms. Thereby, an accelerated clearance of parasitized RBC by the functional spleen could protect those with HbAS, while HbS homozygotes would lose this protection as they acquire functional asplenia. In synergy with this scenario, the presence of HbS impairs endothelial cytoadherence of infected RBC, thereby diminishing cerebral symptoms and impeding the RBC sequestration that would otherwise protect them from splenic exposure. An alternative (or complementary) immune mechanism may be developing antibodies to *falciparum* antigens on the RBC surface.

Additionally, the blunted malarial susceptibility in HbAS reflects complex interrelationships between the sickle gene, other globin genes, host biology, and environmental factors. For example, the protective benefit of HbAS is lost if there is concurrent α thalassemia (which lowers the proportion of HbS). Malarial severity is affected by polymorphisms in non-globin genes such as *CR1* (complement receptor 1), *CD36*, *TGFB1* (transforming growth factor β), *HMOX1* (heme oxygenase 1), and *TLR4* (toll-like receptor 4). Both carbon monoxide (CO) and nitric oxide (NO) blunt the severity of experimental malaria. And certain micro RNAs, enriched in HbS-containing RBC, can inhibit *P. falciparum* growth.

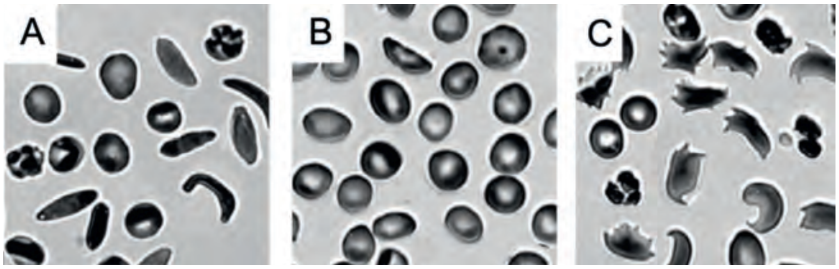

Figure 42.1 SICKLE RED BLOOD CELL (RBC) MORPHOLOGIES. (A) A sickle cell anemia blood smear made directly from venous blood not exposed to oxygen. Smoothly elongated, raisin-shaped, and normal-appearing sickle RBC are present. (B) The same blood fully oxygenated reveals morphology that is largely normal, except for a single irreversibly sickled cell (ISC). (C) Cells from panel B that have now been fully deoxygenated, causing most RBCs to become sickled. The physical–chemical basis for these shapes is presented in Fig. 42.4. *(Reproduced with permission from Obata K, Mattiello J, Asakura K, et al. Exposure of blood from patients with sickle cell disease to air changes the morphological, oxygen-binding, and sickling properties of sickled erythrocytes. Am J Hematol. 2006;81:26.)*

Eventually, the sickle gene spread geographically by means of commerce, migration, and the slave trade. This dispersion has been tracked by analyses of the regional β haplotypes, a biological marker that largely corroborates predictions of gene flow derived from historical records. As a generalization, it spread on the Benin haplotype to North Africa and then across the Mediterranean. All three major African haplotypes are present in the western Arabian Peninsula; but on the eastern side, the sickle gene tends to be on the Arab-India haplotype. This is also true in India, although sub-Saharan haplotypes are represented as well. In the Americas, the β^S gene is mostly found on the Benin, Senegal, and Bantu haplotypes.

ABNORMAL MOLECULAR BEHAVIORS OF SICKLE HEMOGLOBIN

Because the $\beta^{6Glu \rightarrow Val}$ substitution entails a loss of negative charge and gain in hydrophobicity, HbS exhibits three abnormal molecular behaviors of direct relevance to pathophysiology. (See box on Relationship of HbS Molecular Behaviors to Disease Features.)

RELATIONSHIP OF HbS MOLECULAR BEHAVIORS TO DISEASE FEATURES

- Altered dimer assembly → RBC Hb composition
  - Hb phenotype and diagnosis
  - Polymerization risk
- HbS instability → Membrane defects
  - RBC dehydration
  - Hemolysis
  - Malaria resistance
- HbS polymerization → Sickling
  - Vasoocclusion
  - Hemolysis

Hemoglobin S Charge and Tetramer Assembly

The formation of Hb tetramers requires the proximate assembly of stable dimers from unlike monomers (e.g., $\alpha + \beta \rightarrow \alpha\beta$), an event governed by electrostatic attraction. The normal α and β chains are positively and negatively charged, respectively. In heterozygous states for β-globin mutants, β-chain competition for dimer assembly is a determinant of the relative proportions of the Hb variants.[1] Mutant β chains with less negative charge form αβ dimers more slowly; the relative rates for dimer association are $\alpha\beta^A > \alpha\beta^S > \alpha\beta^C$, with $\alpha\beta^A$ dimers formed about twice as rapidly as $\alpha\beta^S$ dimers. This explains why those with HbAS typically have only 40% HbS and why the proportion of HbS exceeds this in HbSC disease. It also explains the effect of concurrent α-thalassemia on the proportion of HbS in sickle trait—availability of α chains becomes limiting, the percentage of HbS typically drops from 40% to 35% (one α deletion), 30% (two α deletions), or less than 25% (three α deletions).

Hemoglobin S Stability and Oxidant Formation

HbS is modestly unstable, observed in vitro as instability to various applied stresses. Two stresses that are most clearly physiologic involve Hb oxidation.[2] HbS has an abnormal redox potential compared with HbA that may underlie its modestly (~40%) increased autooxidation rate. Yet, HbS exhibits markedly (~340%) augmented instability and oxidation upon interaction with aminophospholipids of the membrane's inner leaflet. This instability leads to the accumulation of various Hb and iron forms at the cytosol–membrane interface.[2] The resulting localization of abnormal oxidative biochemistry promotes a number of prominent defects of the sickle RBC membrane. Other contributors to oxidant stress within sickle RBC are addressed later.

Hemoglobin S and Polymerization

OxyHbS, oxyHbA, and deoxyHbA have very high solubilities, but deoxyHbS aggregates into densely packed polymers, a process that is fully reversible upon reoxygenation.[3, 4] This abnormal property, the fundamental pathogenesis of the sickling disorders, causes the eponymous RBC shape to change because of polymer-mediated distortion (see Fig. 42.1).

Polymer Structure

Deoxygenation transforms soluble HbS into a highly viscous and semisolid gel that behaves thermodynamically similar to a crystal in equilibrium with a solution of individual tetrameric Hb molecules. Even complete deoxygenation does not convert all deoxyHbS to polymers. The insoluble phase is a collection of domains of aligned polymers, the basic unit of which is a double-strand in which two strings of deoxyHb tetramers make multiple contacts with each other (Fig. 42.2).

Each HbS tetramer has two β^S chains, the β_1 and β_2. DeoxyHbS undergoes a slight structural shift so that the A helix β^{6Val} "donor" site of the β_2 chain in one tetramer can contact an EF helix "acceptor" site (formed mainly by β^{85Phe}, β^{88Leu}, and β^{70Ala}) in the β_1 chain of a tetramer in the neighboring single string. This critical, lateral association can be made only when HbS is in its deoxy conformation. In HbA this EF helix hydrophobic pocket is not a favorable acceptor site for the charged β^{6Glu} of the β^A. In HbS, the β^{6Val} in the β_1 subunit is located so it cannot participate in such contacts. However, the β_2 chain of the second single string can form chemically similar β^{6Val}-dependent contacts with the β_1 chain of the first single string. There are multiple additional axial and lateral contacts, but these are largely the same for deoxyHbA and deoxyHbS and are not themselves sufficient to stabilize a polymeric structure.

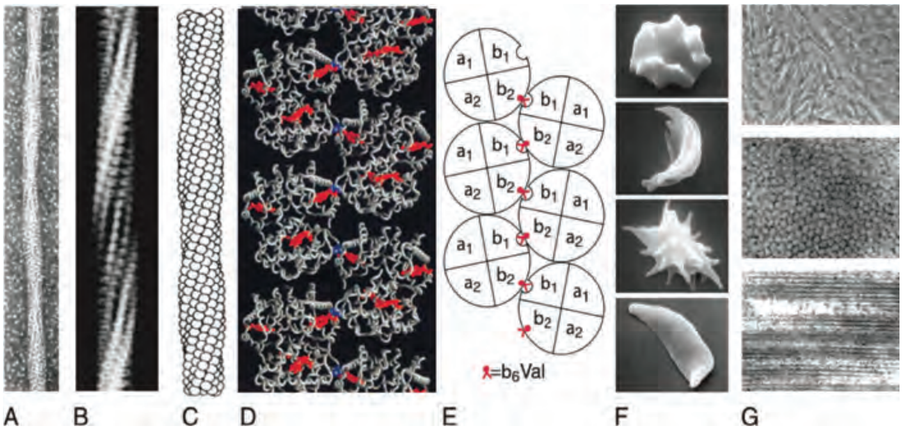

Figure 42.2 DEOXYGENATED HEMOGLOBIN S (HBS) POLYMER. (A) Electron micrograph of a fiber of polymerized HbS. (B) Electron density surface map, modeled from authentic HbS fibers, shows pairings that create double strands plus a helical twist. (C) Model of the HbS fiber, with Hb tetramers rendered as solid spheres. (D) Protein backbone shows tetramer staggering in the HbS crystal. Heme in red, and β^6 valines in blue. (E) Schematic representation of a double-strand (without the twist), emphasizing that only one of the two β^6 valines residing (in red) in each HbS tetramer participates in critical lateral contacts. (F) Sickled red blood cells, showing various morphologies *(top to bottom):* granular, holly leaf-shaped, classically sickled, and irreversibly sickled. (G) Electron microscopy of sickled RBC cytoplasm reveals highly ordered polymer domains, as seen from the side *(bottom)* and on the end *(middle)*, or highly disorganized domains from rapid polymerization *(top)*. *(A and C, Reproduced with permission from Dykes G, Crepeau RH, Edelstein SJ. Three-dimensional reconstruction of the fibres of sickle cell hemoglobin. Nature. 1978;272:506. B, Reproduced with permission from Carragher B, Bluemke DA, Becker M, et al. Structural analysis of polymers of sickle cell hemoglobin. J Mol Biol. 1988;199:315. D, Reproduced with permission from Harrington DJ, Adachi K, Royer WE, Jr. The high-resolution crystal structure of deoxyhemoglobin S. J Mol Biol. 1997;272:398. F and G, Courtesy Dr. James G. White and reproduced with permission from White JG. Ultrastructural features of erythrocyte and hemoglobin sickling. Arch Intern Med. 1974;133:545.)*

In the physiologic form of the polymer, the component strings of HbS molecules in a double-strand are half-staggered and have a slight twist, creating a fiber that is approximately 21 nM in diameter and is composed of one central and six peripheral double strands. The crystal formed in vitro lacks the twist, but its molecular structure is known in great detail.

HbS Solubility

The RBC's hydration state dominates the physical-chemical behavior of HbS. The solubility of deoxyHbS (approximately 16 g/dL, measured under laboratory conditions) is much lower than the RBC mean cell Hb concentration (MCHC, ~34 g/dL). So, even partial cellular deoxygenation can raise deoxyHbS concentration above its solubility limit, allowing polymerization to occur. The biophysical effect of macromolecular crowding (boosting a protein's activity far above that predicted from concentration alone) confers nonideal behavior upon cytoplasmic constituents, augmenting the likelihood for polymerization at any given degree of deoxygenation.

Equilibrium and Polymerization

In vitro studies carried out under (nonphysiologic) equilibrium conditions of stable oxygen tension and long-time scale corroborate crystallographic identification of critical amino acids involved in atomic contacts by revealing the influence of other Hbs on HbS solubility (Fig. 42.3).[3] When different Hbs are mixed together, the tetramers dissociate into dimers that intermix and randomly reassemble in a binomial distribution to reform tetramers. This clarifies the impact of naturally occurring, intracellular Hb mixtures. In a mixture of HbS and HbA, overall solubility is improved because the hybrid $\alpha\beta^S/\alpha\beta^A$ tetramer integrates into polymer only one half as well as the $\alpha\beta^S/\alpha\beta^S$ tetramer (see Fig. 42.3A). The addition of HbF to HbS has a greater sparing effect because neither the $\alpha\gamma/\alpha\gamma$ nor the hybrid $\alpha\beta^S/\alpha\gamma$ tetramer can be incorporated into polymers. In this regard, HbC has the same effect as HbA, and HbA_2 has the same effect as HbF. This sparing effect of HbA is such that much lower Hb oxygen saturation is required for a polymer to form in HbAS than in HbSS RBCs (see Fig. 42.3B).

Kinetics and Polymerization

Laboratory measurements of polymerization kinetics, enabled by inducing (nonphysiologic) near-instantaneous and complete conversion of HbS from R (oxy) to T (deoxy) state, reveal a delay until polymer forms explosively.[4] This inherent delay time is inversely related to an extraordinarily high power of the initial Hb concentration. For example, the delay is 10 ms at HbS 40 g/dL, but it is 100,000 seconds at HbS 20 g/dL (Fig. 42.4A). HbS solutions and sickle RBCs behave similarly in this regard. Delay times must vary enormously from cell to cell because they are dominated by the marked heterogeneity in MCHC (i.e., shorter delay for more dehydrated cells) and are influenced by the presence of any non-S Hb (i.e., longer delay for the presence of HbA, C, or F) (see Fig. 42.4E). Admixture of 20% to 30% HbA with HbS (simulating HbS-β^+-thalassemia) increases the delay time 10- to 100-fold, and admixture of 20% to 30% HbF with HbS increases it by 10^3- to 10^4-fold.

The mechanism of such polymer formation is understood to proceed by a two-step, double-nucleation process (see Fig. 42.4F). Accordingly, the initial homogeneous nucleation takes place in bulk solution, during which small numbers of tetramers associate, with accumulation not favored until a critical nucleus size, develops (estimated to be 30 to 50 tetramers). Only then can new tetramers be added lengthwise to form a large polymer. After this occurs, heterogeneous nucleation causes explosive, autocatalytic polymer formation as new fibers form and extend on the surface of the preexisting polymer. It is the time until this explosive formation occurs that laboratory experiments detect as the *inherent* "delay time."

The striking irreproducibility of long delay times reflects the underlying stochastic formation of a single (or very few) homogeneous nucleation event(s) in cells that form polymer slowly—and thus assume a sickled shape reflecting membrane deformation by highly elongated polymer (see Fig. 42.4B). In contrast, short delay times are highly reproducible and reflect the simultaneous formation of multiple nucleation sites in cells that polymerize rapidly—and thus assume a less dramatic, irregular shape reflecting membrane deformation by multiple short polymer domains (see Fig. 42.4C and D).

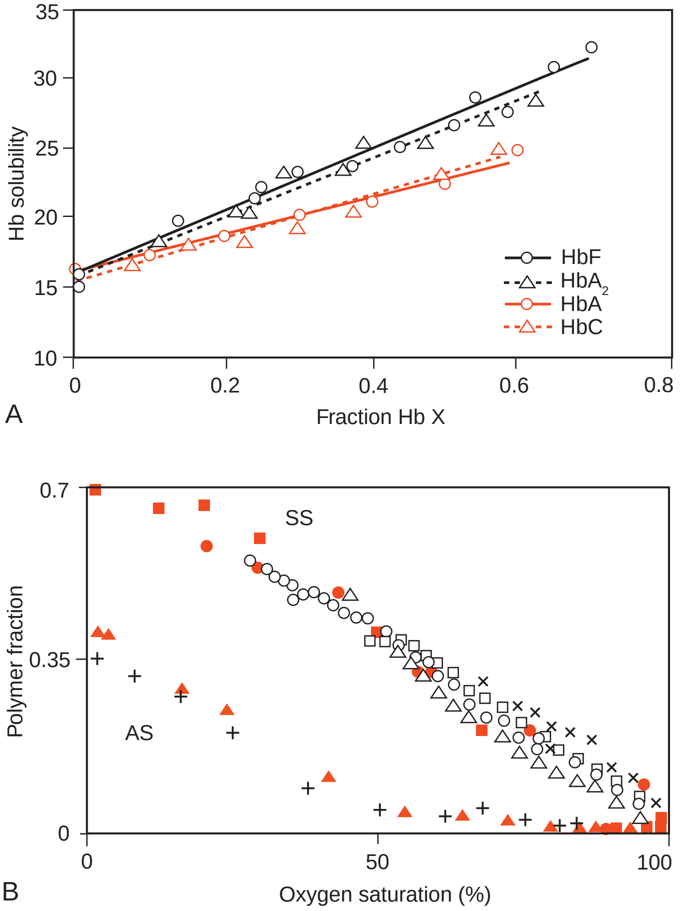

Figure 42.3 DEOXYHEMOGLOBIN S SOLUBILITY, DEFINED BY EQUILIBRIUM STUDIES. (A) Under laboratory conditions, solubility of 100% deoxyHbS is ~16 g/dL. An admixture of other hemoglobins with HbS raises overall solubility in absence of oxygen. The x-axis indicates the proportion of admixed non-sickle Hb. (B) The hemoglobin oxygen saturation required to initiate intracellular polymer formation (i.e., polymer fraction) is much lower for HbAS RBC than for HbSS RBC. *(A, Reproduced with permission from Poillon WN, Kim BC, Rodgers GP, et al. Sparing effect of hemoglobin F and hemoglobin A_2 on the polymerization of hemoglobin S at physiologic ligand saturations. Proc Natl Acad Sci U S A. 1993;90:5039. B, Reproduced with permission from Schechter AN, Noguchi CT. Sickle hemoglobin polymer: structure-function correlates. In: Embury SH, Hebbel RP, Mohandas N, Steinberg MH, eds. Sickle Cell Disease: Basic Principles and Clinical Practice. New York: Raven Press; 1994.)*

Polymerization Under Physiologic Conditions

In physiologic conditions, however, sickle RBCs are neither at equilibrium with constant oxygen tension nor undergoing instantaneous complete deoxygenation. Rather, irrespective of the inherent delay time addressed above, the rate of deoxy-HbS polymer growth in vivo is limited by the rate at which RBC deoxygenation develops during the microvascular passage. Since this transit time is on the order of ~1 second, it effectively renders irrelevant any inherent delay times of more than ~1 second (see Fig. 42.4G).[4] Thus kinetic considerations argue that most RBCs in patients with HbSS are unlikely to sickle during their passage through the microcirculation unless something, such as RBC–endothelial adhesion, slows their transit.

Predictability is complicated by the marked heterogeneity among sickle RBCs in both MCHC and HbF content, as well as the natural biologic variability in capillary transit times. A good qualitative correspondence between polymerization in solution and within RBCs argues that the fundamental polymerization mechanism is not altered by RBC membranes. Yet, emerging evidence suggests that the notably abnormal sickle RBC membrane can accelerate nucleation, in essence eliminating the inherent delay time. A similar effect would be exerted by any preexisting polymer not completely melted during prior pulmonary transit (expected for fewer than 1% of RBCs). However, neither of these effects would alter the physiologic constraint that bulk polymer growth rate can only parallel RBC deoxygenation rate.

In vitro, sickle RBC can become classically sickled or assume holly leaf or granular forms, depending on deoxygenation rate (slow to rapid, respectively), which determines the number of nucleation domains created (see Fig. 42.4B–D). In the microcirculation, granular forms are probably most likely to occur; in contrast, frankly sickled forms are probably more likely to develop in veins. The RBC shape per se is not a determinant of RBC deformability, but rigidification caused by polymer does and, therefore, affects microvascular passage.

HbF and Its Protective Effect

In HbSS, HbF in RBC lysates averages 5% to 8% (range 1% to 25%). However, this HbF is not distributed evenly amongst RBCs.[5] Rather, its heterocellular expression is evident in the presence of F cells (RBC particularly enriched in HbF) that comprise anywhere between 2% and 80% of all RBCs. For most patients, only the small proportion of their F cells that contain at least ~10 pg HbF (roughly one-third of RBC Hb content) are predicted to be protected from polymerization under physiologic conditions.[5] On average, F cells remain better hydrated and exhibit better survival.

Alternative Ligands: CO and NO

Patients with HbSS can have nontrivial elevations of CO-Hb levels (reportedly as high as 7.6% in children) because of hemolysis. Hb that is partially liganded with CO is shifted to the R state conformation but has lost a portion of its oxygen-carrying capacity. RBC and Hb appear to participate in NO transport to the microcirculation, although both magnitude of the effect and mechanisms involved are debated. NO is asserted to improve RBC deformability and impair HbS polymerization. The reaction of NO with oxyHb causes Hb oxidation to metHb and reciprocal consumption of NO.

ABNORMALITIES OF SICKLE RED BLOOD CELLS

Even oxygenated sickle RBCs exhibit a variety of cellular and membrane abnormalities that contribute directly to pathophysiology. Some are the direct consequence of polymer formation, some result from oxidative biochemistry, and some even reflect RBC response to its environment. An overarching theme in sickle disease pathobiology is that individual sickle RBC exhibit remarkable heterogeneity in various cellular characteristics. Their striking variabilities in hydration status (MCHC) and HbF content are particularly important. (See box on Major Sickle RBC Membrane Defects.)

Membrane Iron and Oxidant Generation

An abnormal oxidative biochemistry takes place at the cytosol–membrane interface of the sickle RBC.[2] The avidity of HbS for bilayer lipid, and perhaps its modestly enhanced auto-oxidation in solution, resulting in the augmented formation of superoxide and met-Hb. This, in turn, can readily lose its heme to the lipid bilayer, where it is easily destroyed by lipid hydroperoxides to liberate “free” iron. Forms of iron on the sickle RBC membrane are catalytically active, generating highly reactive oxidants. Also, membrane “free” iron can form a redox couple with soluble oxyHb to promote further Hb oxidation, denaturation, and deposition. The sickle RBC membrane thereby

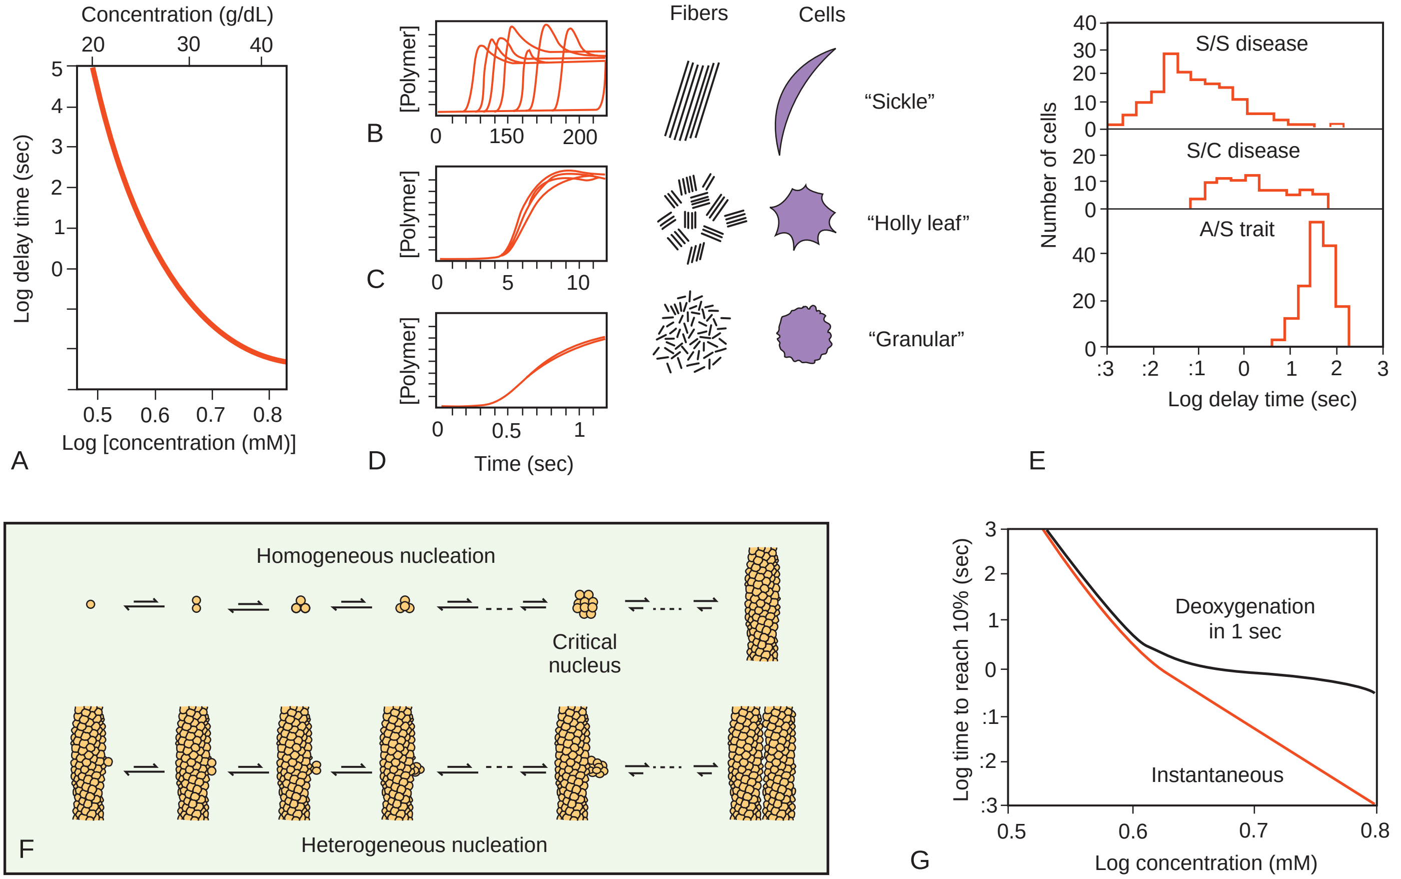

Figure 42.4 KINETICS OF HEMOGLOBIN S POLYMERIZATION AFTER NEAR-INSTANTANEOUS AND COMPLETE DEOXYGENATION. (A) Extreme dependence of delay time on hemoglobin concentration. (B–D) Kinetic progress curves for HbS polymer formation. (B) Long delay times are highly variable, tend to involve a single elongated polymer domain and result in sickle-shaped RBC. (C and D) Short delay times are far more reproducible, tend to involve multiple polymer domains and result in holly leaf or granular shaped RBC. (E) Delay times for individual RBCs are influenced by substituent hemoglobins. (F) A double nucleation process underlies polymer formation, with unfavored homogeneous nucleation *(top)* followed by explosive heterologous nucleation *(bottom)*. (G) Delay times that are short relative to the physiological rate of deoxygenation rate (i.e., ~1 second) are pathophysiologically irrelevant. *(A–E, Reproduced with permission from Eaton WA, Hofrichter J. Hemoglobin S gelation and sickle cell disease. Blood. 1987;70:1245. F, Reproduced with permission from Ferrone FA, Hofrichter J, Eaton WA. Kinetics of sickle hemoglobin polymerization II. acquires abnormal amounts of various iron forms: Hb, denatured hemichrome, free heme, and nonheme iron.[2]

The membrane association of catalytic iron establishes in sickle RBC a unique oxidant risk (not present in normal RBC) because it effectively targets oxidative damage to membrane components. Further, the juxtaposition of iron with bilayer lipid allows re-initiation of peroxidative chain reactions, effectively bypassing protection by vitamin E. Deficient levels of antioxidants (e.g., vitamin E, glutathione, ascorbic acid) in sickle RBC, caused by oxidative consumption and dietary insufficiencies, contribute. The result is abnormal oxidation of membrane protein thiols and peroxidation of membrane lipids. Among the many sickle membrane defects, evidence for an oxidative origin or contribution is strongest for Band 3 clustering, abnormal stiffness, formation of irreversibly sickled cells (ISCs), aberrant cation homeostasis, microvesiculation tendency, abnormal mechanosensitivity, and erythrophagocytosis.[2]

Other sources of oxidant generation by sickle RBC include the reaction of H_2O_2 with metHbS to form membrane-damaging ferryl-HbS. Enhanced activity of sickle RBC nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase exhibits responsiveness to certain plasma substances, for example, endothelin-1 (ET-1). And some oxidant generation derives from retained mitochondria. within sickle RBC.

Cation Homeostasis and Dehydrated Cells

For normal RBCs, MCHC averages ~32 g/dL and varies from 27 to 38 g/dL, with fewer than 1% of cells having MCHC greater than 38 g/dL. In contrast, the MCHC of sickle RBCs averages ~34 g/dL and ranges from 23 to 50 g/dL, with up to 40% of cells having MCHC greater than 38 g/dL. This extreme density heterogeneity results from reticulocytosis (low-density, low-MCHC cells) and dehydrating mechanisms (higher density, high-MCHC cells) (Fig. 42.5).

The most dramatic ion-handling abnormality of the sickle RBC is sickling-induced permeabilization of the RBC membrane to cations (Na^+, K^+, Ca^{2+}).[6] Since this depends on cell deformation, it probably partly reflects, in part, the sickle RBC's exaggerated leak susceptibility to deformation (mechanosensitivity).[2] Sickling induces calcium influx and slight acidification, occurring stochastically and only in some cells at any one time. This results in net potassium and water loss mediated mostly by activation of a Ca^{2+} activated (Gardos) K^+ channel and potassium chloride (KCl) cotransport. The latter can be activated by lowered pH, ET-1, thiol oxidation, and a membrane interaction effect of Hbs that are relatively positively charged (HbC > HbS > HbA). It is influenced by macromolecular crowding of cytosolic proteins caused by the high MCHC. Via its greater membrane association, HbC promotes greater cation loss via KCl cotransport than HbS does, probably the reason HbSC is more severe than HbAS. Even at a steady state, sickle RBCs can contain increased Ca^{2+} because it can be sequestered in cytoplasmic inside-out membrane vesicles, a footprint of prior cytosolic Ca^{2+} transients.

These aberrancies lead to decrements in RBC hydration and deformability.[7] Consequently, hyperdense RBCs—mostly ISCs—are not necessarily older cells with longer histories of sickling and unsickling. Rather, they can develop via a rapid reticulocyte-to-ISC transformation, with those RBC having lower HbF levels being particularly susceptible. It is unclear whether this rapid induction of cation loss or the gradualism of classic interpretations is the dominant mechanism underlying sickle RBC dehydration. Dehydrated RBCs have diminished deformability and an increased propensity for polymerization, the mutually promotive effects of dehydration and sickling comprising a vicious cycle. RBC dehydration is particularly likely to be exaggerated by the renal medullary environment and possibly by nocturnal arterial desaturation accompanying disordered sleep.

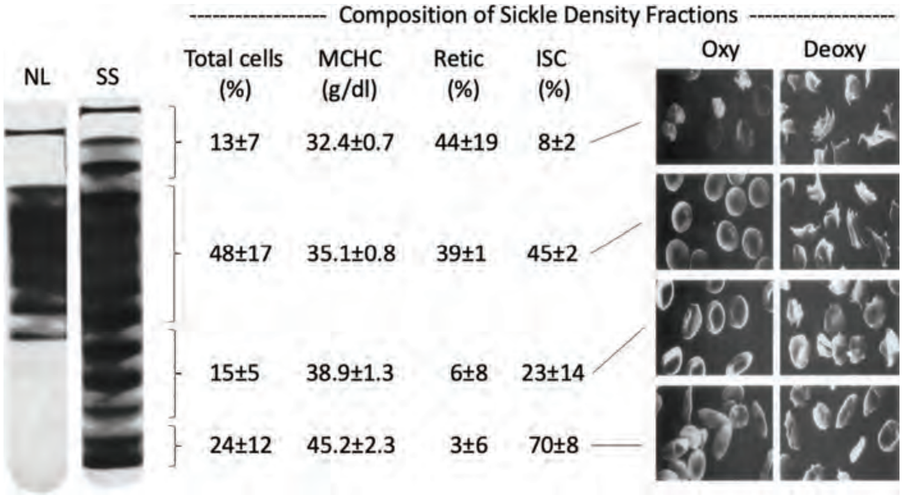
Deformability, Fragility, and Vesiculation

Even oxygenated sickle RBCs are poorly deformable.[7] The dominant cause of this is the abnormally high cytoplasmic viscosity of dehydrated cells. Additional factors include abnormal stiffness of the RBC membrane caused, in part, by protein thiol oxidation and, in part, by a poorly understood direct rigidifying effect of HbS upon the membrane. Upon RBC deoxygenation in vitro, there is a temporal correspondence between the appearance of polymer-induced shape change and deterioration of deformability, as measured by micropipette and laser diffractometer. On the other hand, filtration studies found decreased deformability before the morphologic change, and viscometry reveals a large increase in bulk viscosity caused by deoxygenated dense discocytes that show little shape change.

Sickle RBCs are somewhat mechanically fragile, which may be a consequence of dehydration and a weakening of critical skeletal associations caused by oxidative protein damage. The tendency of sickled RBCs to lose membrane microvesicles reflects the separation of the bilayer from the underlying skeleton due to spicules of polymerized Hb, with enhanced susceptibility caused by protein thiol oxidation.

Membrane Proteins and Lipids

Sickle RBC membrane protein function is adversely affected by excess thiol oxidation and possibly other oxidative protein modifications.[2] Ankyrin interactions with spectrin and Band 3 are abnormal, glycophorin and Band 3 exhibit decreased mobility, and thiol-oxidized β-actin displays abnormal associations in the spectrin–actin-4.1 complex. Band 3 is abnormally clumped from the binding of denatured



Composition of Sickle Density Fractions

Total cells (%)	MCHC (g/dl)	Retic (%)	ISC (%)

HbS, which enables the attraction of naturally occurring anti-Band 3 immunoglobulin (Fig. 42.6). In turn, this promotes engulfment of sickle RBC by macrophages.

Normal enforcement of bilayer phospholipid asymmetry is impaired in sickle RBCs. Sickling promotes PS externalization, especially in ISCs, but also in some reticulocytes. A scramblase that moves phosphatidylserine (PS) outward is activated by calcium transits, and a translocase that restores PS inwardly can be inhibited by thiol oxidation.

Other changes include the presence of peroxidation byproducts such as malondialdehyde (MDA) that can cross-link proteins and promote erythrophagocytosis. Notably, the increased presence of bilayer lipid hydroperoxides appears to account for the sickle RBC membrane's abnormal mechanosensitivity, evident in its enhanced cation leak response to a deforming stress. Perhaps this abnormal deformation susceptibility augments other aberrancies, for example, microvesiculation tendency.

Irreversibly Sickled Cells

The elongated RBCs seen on a typically-obtained blood smear are mostly partially deoxygenated RBCs and ISCs (see Fig. 42.1). The latter's permanent shape abnormality is caused not by persistent polymer but rather by membrane retention of an elongated shape, explained by thiol oxidation of β-actin such that the spectrin–actin-4.1 complex exhibits abnormally slow dissociation. Otherwise, ISCs are similar to other equally dense RBC in having high MCHC, poor deformability, externalized PS, and low HbF content (Fig. 42.5). ISC counts on average are higher in male patients, perhaps reflecting their average lower levels of HbF. The fundamental requirements for ISC formation seem to be RBC dehydration, prolonged deoxygenation, and the assumption of a fixed membrane shape. We suspect that the latter is fostered by a prior deforming and "conditioning" residence in the microcirculation.

The clinical importance of ISCs lies in their ability to prompt diagnosis of a sickling disorder when seen on blood smear, their short life span contributing to overall hemolytic rate, and their participation in the RBC logjam involved in occlusion. Although still adhesive to endothelium, ISCs are less so than other sickle subpopulations, but they exhibit greater adherence to macrophages.

Endothelial Adhesivity

Sickle RBCs are abnormally adhesive to vascular endothelial cells (Fig. 42.7). In vitro studies have implicated about two dozen candidate mechanisms, most involving adhesion molecules on endothelium and sickle RBCs, with or without intermediate bridging by adhesogenic plasma proteins.[8] Some mechanisms require RBC signaling responses to plasma factors, for example, epinephrine, for activation. Some described mechanisms are most evident for reticulocytes and are probably high affinity, identified using flowing conditions. Yet, microcirculatory blood flow can be intermittent and involves constraining vascular diameters that enable greater contact surface area between RBC and endothelium. So it seems plausible that low-affinity adhesive mechanisms could gain relevance in capillaries.[8] To date, only sickle RBC/endothelial adhesion mediated by $\alpha_v\beta_3$ and P-selectin and ICAM-4 (LW) has been verified under flow in vivo in the sickle mouse. An unanswered question is whether or not RBC adhesion in vivo occurs via a single dominant mechanism—or via different mechanisms that can vary amongst patients, locations, and clinical circumstances.

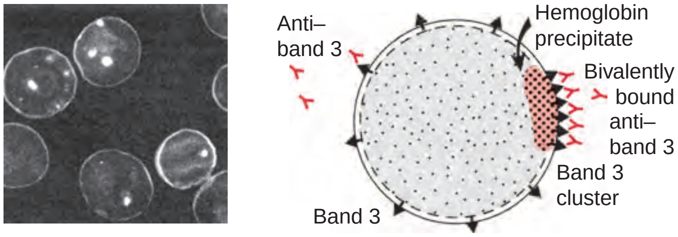

Figure 42.6 BAND 3 AND IMMUNOGLOBULIN COCLUSTERING. Denatured Hb on the RBC membrane causes clumping of Band 3 and opsonization by naturally occurring anti-Band 3 antibodies. Clusters (white spots) of band 3 colocalized with immunoglobulin on the membranes of sickle RBC *(left)*. The drawing shows the colocalization scheme *(right)*. Not shown here is that these changes attract complement and promote erythrophagocytosis by macrophages. *(Reproduced with permission from Schluter K, Drenckhahn D: Co-clustering of denatured hemoglobin with band 3: its role in binding of autoantibodies against band 3 to abnormal and aged erythrocytes. Proc Natl Acad Sci U S A. 1986;83:6137.)*

Macrophage Interaction

Sickle RBCs adhere to and are readily phagocytosed by macrophages because of RBC membrane modifications by malondialdehyde, PS externalization, and opsonization by immunoglobulin. The latter process is triggered by abnormal clustering of membrane protein Band 3 (see Fig. 42.6) and possibly by modification induced by malondialdehyde. The densest cells have the most surface immunoglobulin and higher PS externalization, and they exhibit the greatest interaction with macrophages and the potential for erythrophagocytosis.

DISEASE PATHOGENESIS

Vascular Occlusion

Notwithstanding the conceptual simplicity of the sickling phenomenon, when acute microvascular occlusion causes an acute painful episode it is a complex and evolving process. It seems virtually certain that similar events, but of a less severe degree and remaining at a subclinical level, are a recurrent or even near-constant feature of sickle vascular pathobiology.[9]

Insofar as sickling is responsible, risk factors include anything that can prolong microvascular transit time (e.g., inflammatory milieu, RBC stiffness), increase RBC dehydration and MCHC (e.g., clinical

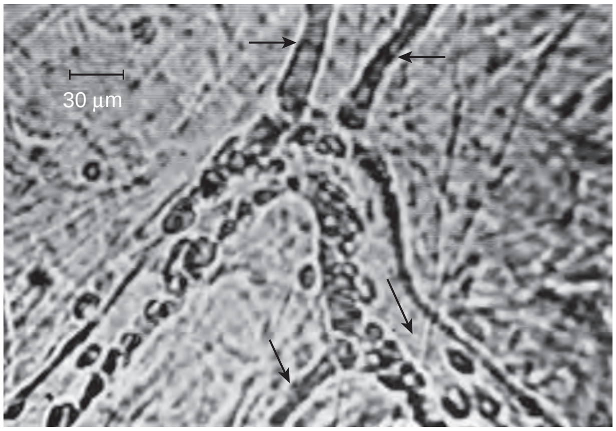

Figure 42.7 SICKLE RBC ADHESION TO ENDOTHELIUM. RBCs adhere to the vascular wall endothelium under flowing conditions in the microcirculation of a rat infused with human sickle RBC. Immobile RBCs are on walls of the postcapillary venule that still is flowing *(long arrow)*. The smaller feeder microvessels *(small arrows)* have no flow because of the logjam of RBC. *(Reproduced with permission from Kaul DK, Fabry ME, Nagel RL. Microvascular sites and characteristics of sickle cell adhesion to vascular endothelium in shear flow conditions: pathophysiological implications. Proc Natl Acad Sci U S A. 1989;86:3356.)*

dehydration, injudicious use of diuretics), foster arterial oxygen desaturation (e.g., lung disease, sleep apnea), increase blood viscosity (e.g., transfusion, inflammation, clinical dehydration), right-shift the oxygen binding curve (e.g., acidosis), or disturb vascular dynamics (e.g., cold, neurochemical responses).

The extraordinary heterogeneity amongst sickle RBCs undoubtedly confers considerable behavioral variability as they lose oxygen while traversing the microcirculation single-file. Such heterogeneity is perhaps the most perplexing feature of sickle disease pathobiology.

RBC Deformability

The diminished deformability of dehydrated (high MCHC) sickle RBC undoubtedly contributes to the impairment of microvascular flow. Some dense cells (especially ISCs) can have difficulty entering the microvasculature, for example, at bifurcations. RBC with lower HbF content will transit with a higher risk of sickling, and HbF level is inversely related to the frequency of vasoocclusive painful crises.[5,10] Low HbF RBCs tend to become more dehydrated (have higher MCHC) and are less deformable.[7] They, therefore, pass within the microcirculation less easily. Nonetheless, among sickle patients vasoocclusive severity correlates positively with preserved deformability, rather than impairment thereof. This probably reflects the higher endothelial adhesivity of more deformable RBC. Whether RBC adhesivity and poor deformability exert synergistic effects within the smallest vessels has not been studied, nor has any role for dynamic change of rigidity during deoxygenation on the timescale of microvascular transit.

Adhesive RBC

The tendency of sickle RBC to abnormally adhere to endothelium slows the microvascular flow. Indeed, in transgenic sickle mice, vascular occlusion is a two-step process: adhesion of less dense (reticulocyte-enriched) sickle RBC to endothelium in the postcapillary venule slows the flow and initiates vasoocclusion via retrograde log-jamming by dense, poorly deformable, and sickling cells (see Fig. 42.7).[11] Consistent with this, among patients clinical vasoocclusive severity correlates positively with the endothelial adhesiveness displayed by sickle RBCs in vitro.[8] To be sure, participation of sickle RBC adhesion in pathophysiology is governed by endothelial activation states. In the sickle context, a multitude of biologic mediators can influence endothelial surface features (see box on The Complex Sickle Milieu).

Adhesive WBC

Consistent with their inflammatory endothelial activation state, sickle mice also exhibit abnormal leucoadhesion to endothelium even at baseline; and when they are exposed to hypoxia/reoxygenation (which triggers a sickling/unsickling response) this is enormously augmented.[12] Just as for adherent sickle RBC, leucoadhesion in post-capillary venules slows microvascular transit of RBC, and blocking this with antibody to P-selectin (but not to E-selectin) greatly improves microvascular flow.[12] On the other hand, in sickle disease WBC, participate in intravascular heterocellular interactions, just as they do in another arteriopathy, atherosclerosis. Also, in sickle mice, it has been observed that when adherent WBC engages E selectin, an activating wave causes them to secondarily capture sickle RBC—but only after massive tumor necrosis factor (TNF) injections.

Hemolytic Anemia

RBC life span in HbSS averages about 15 days, but with marked interindividual variability (from ~7 to ~30 days); in HbSC disease, the average is about 30 days.[13] All four fundamental mechanisms that can underlie premature RBC removal in hematologic disease—erythrophagocytosis, fragmentation, trapping, and osmotic lysis—probably contribute (Fig. 42.8, bottom). These mechanisms derive from the multiple aberrant properties of sickle RBC (see Fig. 42.8, middle) that are consequences of the pathogenic molecular behaviors of the mutant HbS (see Fig. 42.8, top).

This model suggests that the routes to accelerated RBC removal resolve into two contributory mechanistic cascades. One flows from

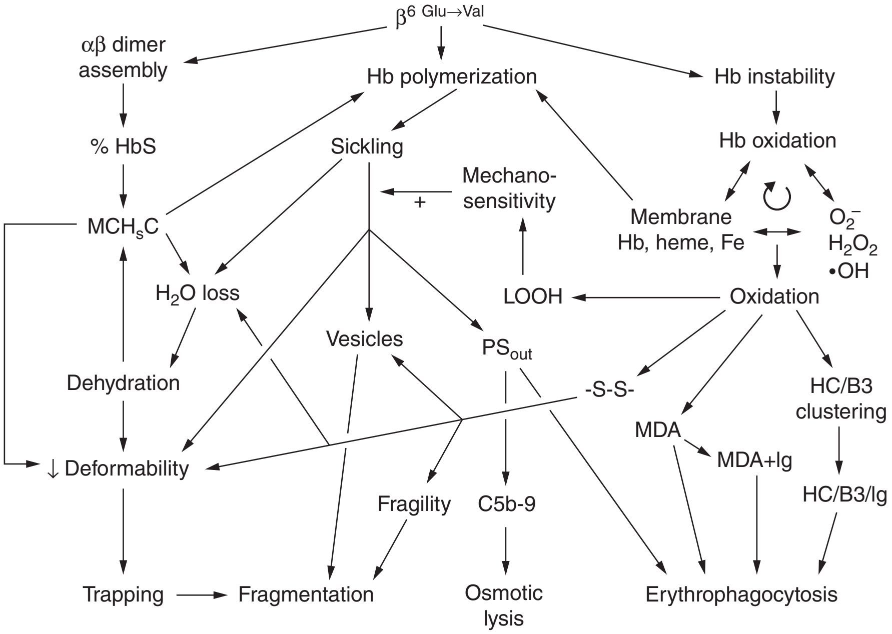

Figure 42.8 MECHANISMS LEADING TO HEMOLYSIS IN SICKLE CELL DISEASE. This integrated synthesis proposes how the distinct molecular behaviors of HbS (*top*) cause the development of multiple sickle RBC abnormalities (*middle*) that, in turn, lead to the four mechanisms of accelerated RBC destruction (*bottom*). *(Modified with permission from Hebbel RP: Reconstructing sickle cell disease: A data-based analysis of the "hyperhemolysis paradigm" for pulmonary hypertension from the perspective of evidence-based medicine. Am J Hematol. 2011:86:123–154.)*

polymer formation and underlies RBC trapping, fragmentation, and osmotic lysis, causes of intravascular hemolysis. The other cascade flows from HbS instability and underlies erythrophagocytosis, the cause of extravascular hemolysis. Although speculative, the illustrated integrated synthesis of extant research data presents a plausible mechanistic blueprint.[13] The proportionate contributions of intravascular versus extravascular hemolysis to the overall hemolytic rate have never been determined. These may vary amongst individuals and with clinical context, just as the net hemolytic rate does. For example, sickle RBC survival drops substantially during acute painful episodes, but whether this precedes or follows vasoocclusion onset is not known.

The shortest survival is exhibited by sickle RBCs that are most dehydrated and that have the lowest amounts of HbF,[14] consistent with the polymerization-based abnormalities (see Fig. 42.8, left side). Yet, it is not known whether these two RBC features fully explain the very wide range of hemolytic rates. Presumably, the sickle RBCs' fragility is related, and sickled RBCs do lose Hb via microvesiculation. Improved RBC hydration caused by concurrent α-globin gene deletion improves RBC survival.[15]

The only biomarkers so far documented to correlate significantly with *measured* RBC life span in HbSS are the (uncorrected) reticulocyte percentage and HbF level.[13] As for lactate dehydrogenase (LDH) as a putative hemolysis severity biomarker, the only available data show that LDH level does *not* correlate with measured sickle RBC survival. Despite this, associations with LDH are what the "hyperhemolysis" hypothesis is based on (see section on Concept of Hyperhemolysis, later).

THE UNIQUE SYSTEMS BIOLOGY OF SICKLE CELL ANEMIA

HbSS is unique amongst human diseases in its extraordinary complexity with a highly aberrant milieu (see box on The Complex Sickle Milieu). Remarkably, this state derives from only two proximal events that are interrelated and mutually promotive, vasoocclusion/ischemia-reperfusion (I/R) and hemolysis. Although it is not possible to identify their proportionate contributions to pathogenesis, our view is that ischemia/reperfusion and hemolysis likely exert co-dominant impacts. Indeed, HMGB1 (high mobility group box 1) from ischemia/reperfusion and free heme from hemolysis biologically converge at TLR4 inflammatory signaling (Fig. 42.9).[9]

Ischemia-Reperfusion Physiology

Sickle transgenic mice reveal that proximal instigation of endothelial activation derives from I/R injury (Fig. 41.10).[9] The complicated biology of I/R can occur when vascular ischemia is followed by reperfusion that reintroduces oxygen to the formerly ischemic area. In the unique sickle context, the initiating occlusive events are likely to be microvascular and multifocal, and they occur recurrently, possibly incessantly. Consequently, sickle transgenic mice exhibit the reperfusion-dependent, classical, early I/R processes: localized and rapid onset of oxygen radical generation, complement activation, nuclear factor kappa-B (NFκB) activation, the release of HMGB1, production of TNF-α, and local activation of leukocytes and mast cells. This results in local I/R injury, i.e., extension of tissue injury beyond the volume affected by the inciting ischemia itself. In HbSS, this most clearly participates in the genesis of stroke, damage to the kidney and liver, and post-priapism damage, for example.[9]

Thereafter, I/R pathobiology can explosively arborize, seen in HbSS as the chronic, systemic inflammatory state that is unique in its cyclicity, complexity, instability, and perpetuity. Specifically, inflammation begets adhesion/occlusion begets inflammation (Fig. 42.10). This robust systematization of inflammation promotes the multitude of vascular biologic abnormalities in HbSS, including endothelial dysfunction and arterial vasculopathy. In addition, remote organ injury can develop at a site remote from a triggering I/R injury site, the most common manifestation being an acute lung injury syndrome, such as the acute chest syndrome (ACS) of sickle disease.

THE COMPLEX SICKLE MILIEU

Anemia (altered wall shear stress, tissue hypoxia, HIF-1 signaling)
RBC abnormalities (rigidity, sickling, fragility, adhesivity)
Hemolysis (plasma Hb and heme, RBC microparticles, arginase, oxidized lipid)
Ischemia/reperfusion physiology
Blood cell activation (signaling and adhesive interactions with endothelium)
Systemic inflammation:
    TLR4 activators (HMGB1, free heme)
    Other mediators (TNF, IL-1β, MCP-1, PAF, thrombin, leukotrienes, and many others)
    Endothelial glycocalyx degradation
    Activated monocytes, granulocytes, and lymphocyte subsets
    Microparticles (endothelial, monocyte, platelet)
    Mast cell activation (neuroinflammatory mediators)
    NETs
Oxidant stress (Hb oxidation, activated WBC, xanthine oxidase, NADPH oxidase, mitochondrial, others)
Growth factors (VEGF, PIGF, erythropoietin, others)
Dehydration (viscosity, vasopressin)
Hemostatic system abnormalities:
    Coagulation activation (thrombin, others)
    Fibrinolysis (D dimer, others)
    Platelet activation (platelet microparticles, plasma TSP, others)
Vasoactive agents (hypoxia, ET-1, thromboxane, vasopressin, prostaglandins, adrenergic agonists, peroxides, CO, NO, and others)
Adhesogenic proteins in plasma (TSP, ultra-large vWF)
Endothelial cell activation (pro-inflammatory, pro-coagulant phenotype)
Endothelial dysfunction (vasoregulatory aberrancy, pro-inflammatory/coagulant phenotype, barrier leakiness)
Endothelial cell injury
Inadvertent effects of therapies (iron overload, opioid-enhanced angiogenesis signaling)

Hemolysis

Hemolysis exerts plethoric adverse effects, both indirect and direct. The accompanying expanded erythropoiesis enhances the production of adhesive reticulocytes and augments the elaboration of placental growth factors. This mediator activates blood monocytes to promote the production of ET-1 that, in turn, can induce vasoconstriction, cause nociceptive hypersensitization, activate RBC NADPH oxidase activity, and prompt the release of inflammatory mediators. Released cell-free oxyHbS is rapidly converted to met HbS that easily loses its heme,[2] which is then able to initiate inflammatory injury responses such as oxidization of blood and membrane lipids, injuring endothelial cells, activating blood monocytes to produce TNF-α and express tissue factor (TF), and triggering disgorgement of neutrophil extracellular traps, among other effects. Some pathogenic responses to heme are mediated by its binding to TLR4; for example, in sickle mice, this causes enhanced endothelial surface expression of P-selectin and triggers vascular stasis.[16] Released RBC arginase lowers plasma arginine somewhat, hypothesized—but unlikely—to impede endothelial nitric oxide synthase (eNOS). Released PS-positive RBC microparticles can exert an inflammatory signaling impact upon endothelial cells, accelerate thrombin generation, and promote pulmonary sequestration of WBCs.

Figure 42.10 ISCHEMIA/REPERFUSION AS A CORE DRIVING FORCE IN SICKLE CELL ANEMIA. As the consequence of vasoocclusion, ischemia-reperfusion comprises an incessant driving force causing systemic inflammation with microvascular dysfunction. The adhesion biology resulting from activated/dysfunctional endothelial cells slows microvascular transit of sickle RBC and WBC, thereby establishing a positive feedback loop that slows microvascular transit, increasing the likelihood of polymer formation. *(Reproduced with permission from Hebbel RP, Belcher JD, Vercellotti GM. The multi-faceted role of ischemia/reperfusion in sickle cell anemia. J Clin Invest. 2020;130(3):1062–1072.)*

Cell-free Hb derived from lysing sickle RBC can consume NO.[17] This contributes to the NO biodeficiency of sickle disease, and this specific process can *mimic* some features of endothelial dysfunction; for example, it limits NO's vasodilatory and superoxide buffering functions, and it weakens NO's normal braking effects on platelet activation and inflammation. In the sickle context, any potential effects of liberated cell-free Hb/heme are substantially augmented due to the markedly low levels of scavenging proteins, haptoglobin and hemopexin.

Concept of Hyperhemolysis

The "hyperhemolysis" hypothesis argues that HbSS patients having the highest hemolytic rates develop a specific subset of complications (stroke, leg ulcer, priapism, and pulmonary hypertension) caused by a unique mechanism, the accompanying greater consumption of NO.[18] However, support for this concept is limited to an association between these complications and the level of LDH. So, it is notably problematic that correlative association says nothing about causality and that the sole relevant study found that LDH level does *not* correlate with the *measured* hemolytic rate in sickle subjects. Therefore, in our view, the artifice linking higher hemolysis to NO biodeficiency to certain specific complications is, rather, more parsimoniously explained by the well-known, simple fact that greater hemolysis-driven anemia lowers blood viscosity, thereby lessening the likelihood of vasoocclusion-instigated disease in high-hemolysis patients.

INFLAMMATION

Characteristic footprints of the chronic, systemic inflammatory state in HbSS[19] include leukocytosis; activation of granulocytes, monocytes, lymphocyte subsets, and mast cells; elevated levels of inflammatory mediators, acute-phase reactants, and distal effectors; abundance of soluble adhesion molecules; co-activation of coagulation and platelets; the presence of microparticles from multiple activated cell types; and generation of excess oxidant via multiple mechanisms. Importantly, in humans with HbSS, footprints of inflammatory activity are apparent and fluctuate chaotically, even when far removed from any acute clinical events – further evidence that the sickle inflammatory state is perpetual and subject to repeated re-incitement.

The complex sickle milieu, fashioned by effects of I/R and hemolysis, includes many factors that directly or indirectly or interactively promote inflammation and its consequences (see box on The Complex Sickle Milieu). It is impossible to identify proportionate contributions of the innumerable specific inflammatory inputs, and in any case, their relative influences undoubtedly change over time, and they are highly interactive. As but one example, the growth factor angiopoietin-2, released from Weibel-Palade bodies, sensitizes the endothelial cell toward TNF and consequent adhesion molecule expression. Interestingly, a recent study suggests that part of the pro-inflammatory thrust of sickle disease is a failure of normal inflammation resolution mechanisms.

Clinically, leukocytosis in HbSS is a risk factor for mortality, clinical and silent stroke, and ACS, and it helps predict which babies will develop a severe clinical course. Conversely, several clinical complications are themselves overtly inflammatory in nature, in particular acute painful episodes and ACS. But other consequences of chronic inflammation, for example, promotion of arterial vasculopathy, are far more insidious.

Endothelial Activation and Dysfunction

The vascular endothelial cell receives and integrates disparate inputs, both sensing and modifying its environment, normally in an adaptive fashion. In the sickle context, the extreme complexity of the sickle milieu (see box on The Complex Sickle Milieu) molds endothelial cell function, leading to a maladaptive state. The core inflammatory and oxidative inputs cause a high level of endothelial activation and dysregulation, with adverse consequences such as the assumption of a pro-adhesive and pro-coagulant phenotype, vasoregulatory dysfunction, and probable degradation of the endothelial glycocalyx (a critical determinant of endothelial cell homeostasis).

An often-overlooked principle predicts that endothelial dysfunction in the sickle context creates a unique risk (see Mortality and Sudden Death, later).

Aberrant Vasoregulation

HbSS involves deficient endothelial-dependent, flow-mediated conduit artery dilation.[20] NO bioavailability seems to be higher for females than males, who exhibit substantial non-NO regulation of flow. In the context of I/R and inflammation-induced endothelial dysfunction, there undoubtedly are multiple contributing processes that are known to induce dysfunction of eNOS.[9, 13] In sickle disease, these include the following.

TNF-α induces endothelial L-arginase, limiting the availability of intracellular L-arginine for eNOS function. NADPH-oxidase derived excess intracellular superoxide depletes an essential eNOS cofactor, tetrahydrobiopterin. An endogenous eNOS inhibitor, asymmetric dimethylarginine, is elevated. Multiple other dysfunction-inducing factors are extant: oxidized lipids, activated platelets, thrombin, abnormal shear stress, microparticles.[13] Although unstudied in the specific sickle context, a highly likely contributor to eNOS dysfunction is the glycocalyx degradation that invariably accompanies inflammation generally and I/R specifically. Indeed, the normal integrity of the endothelial glycocalyx is an absolute requirement for the mechanosensing of shear stress that adaptively activates eNOS.[9] Since each of these factors individually can cause eNOS dysfunction, their proportionate contributions to endothelial dysfunction in sickle disease are unknowable—and their impacts undoubtedly vary with time and amongst patients.

Perfusion patterns are complex in HbSS but can manifest as impaired microvascular flow concurrent with the augmented macrovascular flow.[21] Aberrancy of both endothelial-dependent and endothelial-independent vasoregulation is apparent, and the milieu is replete with a multitude of vasoactive substances. A state of vascular instability may derive from tonic upregulation of both vasoconstrictive and vasodilatory systems, in addition to exaggerated α_1-adrenergic vessel wall responsiveness. Sickle humans exhibit disruption of autonomic regulation (e.g., with augmented risk for hypoxia-induced perfusion decrements).[22] Systemic blood pressure in patients with HbSS is lower than in nonanemic controls, yet is higher than in comparably anemic β-thalassemics.

Coagulation Activation

The well-known interplay between inflammation and coagulation is evident in HbSS, with chronic activation of coagulation, fibrinolysis, and platelets.[23] This is accompanied by increased whole blood TF and its increased expression on endothelial cells and blood monocytes. Multiple stimuli can contribute to this, including signaling via TLR4. The presence of PS on released microparticles and some sickle RBC promotes accelerated thrombin generation, which appears to be ongoing. Levels of endogenous anticoagulants are deficient. The oxidation appears to create resistance to cleavage of ultra-large forms of von Willebrand factor by ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). There is excessive consumption of antithrombotic proteins. The biodeficiency of NO would contribute to TF expression and augmented platelet activation because it normally inhibits these. Products of platelet and coagulation activation undoubtedly exert signaling and perturbing effects on endothelium.

Genesis of Clinical Disease

The spectrum of clinical involvements in HbSS is remarkable (see Chapter 43). For the individual patient, *evident* clinical disease may not parallel—or accurately predict—the extent of the underlying overall disease burden. That different processes may contribute to different degrees to specific clinical complications is possible,[18] but our view is that both I/R and hemolysis contribute to everything. In any case, the dominant pathogenic influence is the robust systemic inflammatory state, fashioned by the complex milieu such that multiple biologic systems are aberrantly and concurrently activated. Consequently, the vascular endothelium is exposed lifelong to a uniquely perturbing milieu. As the interface between blood and tissues, the endothelium undoubtedly participates significantly, if not dominantly, in the genesis of all clinical complications.

Pain Syndromes

In adults, a higher frequency of acute painful episodes is associated with increased mortality,[9] presumably reflecting derivation of both from the severity of underlying disease activity. The immense further disturbance of multiple biologic processes during acute painful episodes probably augments the risk for associated complications like ACS and sudden death. Pain frequency is higher in association with higher hematocrit and lower HbF levels, consistent with the concept that acute painful episodes involve ischemic pain from vasoocclusion. However, pain in sickle disease appears to be multimodal and complex. In particular, there is a substantial inflammatory contribution to both acute and chronic sickle pain via neuropeptides and mast cell products.[24] Many sickle patients exist in a state of nociceptive hypersensitization, a known potential complication of I/R pathobiology. The chronic, daily pain affecting many patients seems to be both inflammatory and neuropathic in origin.

Chronic Vasculopathy

A prominent feature of the sickle disease is macrovascular in nature, a chronic inflammatory arteriopathy.[19] Most supporting histopathology is from the large and medium vessels at the circle of Willis. Pathologic features are those of intimal hyperplasia, the vessel wall's typical response to inflamed endothelium. In sickle disease, this arteriopathy affects the spleen, umbilical cord, lung, bowel, kidney, and penis. The specific generative stressors for vasculopathy may vary somewhat from organ to organ, but it seems likely that universal contributors include perpetual inflammation and anemic hyperemia causing aberrant (i.e., "atheropromotive") wall shear stress.

Thrombosis

The sickle hypercoagulable state is accompanied by a clinical thrombotic diathesis.[23] In situ arterial thrombosis occurs in areas of vasculopathy in the circle of Willis and lungs exhibiting pulmonary hypertension. Incidence of venous thromboembolism is increased, and HbSS is a complicating condition for pregnancy. Downstream consequences of the coagulation system activation may play a greater role than is currently appreciated. For example, thrombin activates endothelium via protease-activated receptor-1, triggering exocytosis of vWF and P-selectin that underlies abnormal adhesion of sickle RBC and WBC to endothelium.

Stroke and Cerebrovascular Disease

Several stroke syndromes occur in sickle disease and may have somewhat differing pathogeneses. Ischemic stroke with clinical deficit develops in 8% of children with HbSS, in some patients accompanied by prior occlusive vasculopathy at the circle of Willis. The case has been made for causation derived from the combination of anemic hyperemia (a known inducer of middle cerebral arteriopathy), chronic vascular wall inflammation, and vascular anatomy at that particular site.[9] Evolution of this stroke type undoubtedly involves an I/R component, a classical aspect of ischemic stroke pathobiology. Completion of the actual stroke sometimes involves thrombosis at the site of vessel wall disease. A deficiency of clinical research on this problem has been looking for associations with "stroke" rather than associations with its likely underlying generative factors. Concurrent α-thalassemia or HbSC disease lowers the risk of this stroke type, and HbF level is not protective. It can be suspected that elevated growth factors are participants in arterial wall disease and the sometimes-associated moya moya.

In a seemingly separate syndrome, "silent" strokes accumulate throughout childhood and into adulthood. They derive from inadequate microvascular blood flow, typically in transitional white/grey matter locations. Indeed, systemic endothelial dysfunction extends to the brain, rendering deficient the sickle patient's cerebrovascular reserve. Such strokes are not truly silent; rather, they establish lifelong cognitive deficits. Interestingly, silent stroke, hemorrhagic transformation of ischemic stroke, and cognitive deficits all are fostered by endothelial dysfunction at the blood-brain barrier causing hyperpermeability. This is a known aspect of I/R[9] and is a feature of the brain in both sickle mice and humans.

Young adults have an increased risk for hemorrhagic stroke. Underlying causes can be vessel fragility associated with moya moya, endothelial hyperpermeability, and aneurysm.

Pulmonary Disease

The spectrum of sickle pulmonary complications includes chronic restrictive lung disease, pulmonary hypertension, asthma, infection, in situ and embolic thrombosis, and ACS.

The inflammatory ACS is associated with infection in children and sometimes with fat embolism in adults, but additional presumptive triggers are similarly implicated via association. Most notably, the nature and occurrence and timing of ACS during acute vasoocclusive episodes perfectly matches the acute lung injury syndromes that present as a remote organ injury complicating I/R physiology.[9] In the sickle context, a predisposition for this syndrome likely derives from chronic inflammation, abnormal adhesion biology, NO deficiency, TNF-driven endothelial permeability, I/R-driven mast cell activation, and especially the multiple unique features of the pulmonary microvasculature.[9] Chronic pulmonary mast cell activation is a candidate contributor to the asthma prevalence in sickle disease.

Pulmonary hypertension occurs in about 6% of adults with HbSS,[25] in half from pulmonary arterial disease and half from pulmonary venous disease. Genesis is undoubtedly multifactorial, as the sickle context involves multiple features strongly associated with pulmonary hypertension in the general population. These include the absence of splenic function, presence of activated platelets, a chronic systemic inflammatory state, endothelial dysfunction, and a surfeit of growth factor signaling. Indeed, the pulmonary arterial wall in HbSS is awash with suspect mediators, and the NO biodeficiency emasculates a normal braking mechanism on inflammation, proliferation, and vasoconstriction. The pulmonary artery also is uniquely buffeted by the pre-sickled RBC in venous blood; experimental sickle RBC contact with endothelium induces an injury response.

Sleep apnea with nocturnal hypoxia is not uncommon in sickle patients, and of course, hypoxia is a classical pulmonary vasoconstrictor. We suggest this comprises a mechanism that can explain sudden death in sickle disease (see below).

Kidney Disease

In HbSS, renal hyposthenuria is a nearly universal problem arising from medullary hypoperfusion resulting from its harsh, polymerization-promoting renal medullary environment (hypoxia, acidosis, hyperosmolarity). Indeed, this occurs in HbAS as well. The renal cortex, on the other hand, exhibits hyperperfusion, believed to underlie glomerular dysfunction with albuminuria.[21] Patients can also develop an acute renal injury, papillary necrosis, and chronic renal disease, the latter being a significant contributor to mortality and a known consequence of I/R in general medicine. Hematuria from papillary damage is very common.

Mortality and Sudden Death

The mortality rate is higher in HbSS patients having higher rates of acute painful episodes,[26] with notable risk indicators including low HbF, high WBC count, chronic renal failure, and elevated tricuspid regurgitant jet velocity. Among apparent causes of death at autopsy, cardiopulmonary disease is most prominent.[27] Prophylactic penicillin for children has greatly improved the average life span in sickle. Further improvement has derived from chronic use of hydroxyurea, an agent that boosts HbF level, lowers WBC count, improves RBC hydration and survival, and blunts inflammatory biology and RBC adhesivity. Unfortunately, survival remains much worse in parts of the world with less access to medical care and abundant comorbidities (e.g., malaria, diarrheal disease).

HbSS entails an abnormal risk for sudden death, tending to occur during painful episodes. We have hypothesized that this is a direct consequence of the pre-existing, underlying endothelial dysfunction of sickle disease.[13] In that context, arterioles can exhibit exaggerated vasoconstrictive responses if potential constrictors are superimposed, for example, hypoxia, augmented NO consumption, or inflammatory signaling. Each can fluctuate on a short time scale, for example, during acute painful episodes, and thereby might create a risk for sudden death by suddenly elevating right heart pressure.

BASIS OF PHENOTYPIC DIVERSITY

Factors aside from HbS itself undoubtedly contribute to the remarkable inter-individual diversity of clinical phenotype in HbSS, but only a few have been identified thus far. Phenotypes could be significantly influenced by the environment, nutrition, socioeconomic status, endemic infectious agents, and availability of medical care. It is believed that phenotypic variability is most evident in countries where the survival of sickle patients is longer. The innumerable questions regarding phenotypic diversity are of great importance. In HbSS, why do some children, but not others, develop stroke? Why do only a small fraction of adults develop pulmonary hypertension, even though all have ongoing hemolysis? Why does pain severity vary so remarkably irrespective of globin genotype? And so on.

Level of Hemoglobin F

HbF level varies amongst individuals as a quantitative trait and is determined by approximately 80% by genetics.[5] After its decline over the first 6 months of life, most of the anti-sickling protection from its high level at birth is lost. HbF level varies among sickle adults over a 20-fold range, and this reflects the number of F cells, the amount of HbF per F cell, and the preferential survival of F cells.[14] It is estimated that a given sickle RBC requires >10 pg HbF for polymerization to be effectively inhibited.[5]

Known HbF determinants account for perhaps one-half of its variance: a polymorphic *XmnI* site (11p) upstream of the Gγ gene; the *HBSIL-MYB* intergenic region (6q23); SNPs in *TOX* (8q12.1); and polymorphisms of *BCL11A* (2p16), a transcriptional silencer of the *HBG* gene.[5] HbF is somewhat higher levels in females, hinting at a contributing locus on the X chromosome. Polymorphisms in trans-acting enhancers of *BCL11A* account for some, but not all, of the regional variations in the HbF level. Among the African autochthonous haplotypes, the Benin haplotype is associated with higher HbF levels; however, it is twice again as high among those with the Arab-India haplotype.

α-Thalassemia

The normal genotype is αα/αα, but about 30% of African Americans have a single α deletion (-α/αα), so concordance with sickle cell disease is common; and homozygosity for the allele is seen (–α/–α). Its prevalence elsewhere varies regionally. An α-gene deletion has minimal effect on the HbF level but results in improved RBC hydration, a lower ISC count, improved RBC survival, and less severe anemia.[15] Perhaps the loss of one α gene nudges α/β chain balance toward normal, given the mild instability of β^S globin.[2] Yet there is no amelioration of pain severity, and some complications (osteonecrosis, retinopathy) increase, possibly because of the higher blood viscosity.

β-Globin Alleles

Compound heterozygosity for the sickle gene and another β allele affects clinical phenotype, for example, in the direction of amelioration from admixing β^C or β^{+thal} chains with β^S. The resulting HbSC disease, however, presents a unique case. Although HbC impedes HbS polymer formation as well as HbA (see Fig. 42.3A), HbSC disease is more similar to HbSS than it is to HbAS. The reason is that HbC interacts more with the RBC membrane than HbA does, and it thereby stimulates RBC KCl cotransport, promoting RBC dehydration that increases HbS concentration.[28] Although pain and anemia are lessened a bit in HbSC disease, there is an increased propensity for retinopathy and osteonecrosis. It has been assumed that this derives from the somewhat higher blood viscosity when anemia is less severe. HbSC blood reveals footprints of greater pro-angiogenic tone compared to HbSS blood, consistent with the higher propensity for retinopathy. Other less common β gene alleles can likewise interact with HbS and affect clinical phenotype via impact on polymerization.

HbAS is typically associated with renal hyposthenuria, not surprising given the several polymer-promoting influences of the renal milieu. More seriously, trait comprises risk for exertional sudden death, probably precipitated by effects of dehydration on RBC and blood viscosity. At an epidemiologic level, the trait also involves a heightened risk for thromboembolism and chronic renal disease, and it predisposes toward ischemic stroke. It is relevant that, unlike Hb tetramers that include either aγ or a β^{A2} globin chain, tetramers that include a β^A or a β^C globin chain are only partially inhibited from participating in polymerization (see Fig. 42.3A).

Unexplained Phenotypic Diversity

Beyond these well-defined influences, there is still enormous unexplained variability in the clinical phenotype of HbSS. The disparate biologic processes that participate in SCA pathophysiology highlight the certainty that phenotypic heterogeneity will be influenced by underlying genetic variations affecting adhesion biology, cation homeostasis, inflammatory signaling, vasoregulation, and so on. Indeed, the spectrum of potential foci at which genetic variation might exert effects and be relevant to sickle disease phenotypic diversity is as vast and complex as human biology itself.

The single-nucleotide polymorphisms (SNPs) that have been detected in association with specific clinical complications are far too numerous to describe here.[29] Of course, much work is still needed to discern whether such associations are actually informative vis à vis pathogenic specifics. However, several SNPs seem particularly interesting. A TNF (-308) promoter polymorphism is associated with large vessel stroke in sickle children. Polymorphisms affecting the HO-1 promoter create heterogeneity in GT repeat lengths (the shorter of which enable greater HO-1 responsiveness, e.g., to heme) and are described as being associated with a lower hospitalization rate for ACS in children. Interestingly, a TLR4 polymorphic haplotype prevalent only in sub-Saharan Africa leads to greater inflammatory responsiveness to TLR4 ligands; it is protective in malaria, but it could well adversely impact sickle biology. Similarly, the Duffy null phenotype prevalent in Sub-Saharan Africa appears to confer heightened severity for acute lung injury; its presence may likewise promote ACS in sickle disease.

A wholly different approach to this general problem was provided by examination of gene expression and inflammatory response of endothelial cells derived from living subjects. Those from sickle children with circle of Willis disease predicted an augmented inflammatory response, that was experimentally verified as an exaggerated NFκB activation response to stimulation with TNF/IL-1.[30] Certainly, the contribution of various non-globin genetic influences will continue to be identified as modern and creative approaches are being applied to the problem of phenotypic diversity in HbSS.

CHAPTER 43

CLINICAL ASPECTS OF SICKLE CELL DISEASE

Laurel A. Menapace and Swee Lay Thein

Hemoglobinopathies are the most common genetic diseases in humans. In sickle cell disease (SCD), a single nucleotide substitution (GTG for GAG, *rs334*) in the sixth codon of the β-globin gene produces an abnormal sickle hemoglobin (HbS). Due to a change in the convention for numbering amino acid residues in the human β-hemoglobin chain, the HbS mutation becomes E7V rather than E6V and the current numbering puts the HbS mutation in codon 7 rather than 6. In addition to homozygosity for the HbS allele (HbSS), the phenotype of SCD encompasses other genotypes including HbSC (compound heterozygosity of HbS with HbC), and HbSβ-thalassemia (HbSβ^0 or HbS β^+-thalassemia, depending on the type of the β-thalassemia mutation) and rarer genotypes of HbS with hereditary persistence of fetal Hb (S/HPHH), HbS/HbE syndrome, as well as compound heterozygosity of HbS with HbD Los Angeles, HbO Arab, G-Philadelphia, and others.[1]

All of these SCD genotypes have in common at least 50% HbS, the level of which is a key determinant of the SCD severity. Hence, HbSS and HbSβ^0 thalassemia, which have the highest proportion of intracellular HbS fraction (80% to 96% of total Hb), commonly referred to as sickle cell anemia (SCA), generally have a more severe disease course compared to the other SCD genotypes but even within each genotypic and ethnic group, a spectrum of clinical variability exists. Key contributors to observed clinical variability include environmental factors (weather, nutritional status, and access to social and medical support) and genetic background. Co-inheritance of α-thalassemia and genetic determinants of persistent fetal hemoglobin (HbF) production are established major genetic modifiers of SCD.[2]

The key mechanism underlying SCD is polymerization of HbS under deoxygenated conditions altering the shape and function of red blood cells (RBCs). These "sickled" red cells initiate a series of events and the clinical hallmarks of the disease that include chronic hemolytic anemia and recurrent vaso-occlusive (VOC) episodes causing pain, acute chest syndrome (ACS), hepatic or splenic sequestration, and priapism. The end result is chronic organ damage from both microvascular and macrovascular vaso-occlusion. Once a disease with a high childhood mortality, improved childhood survival in well-resourced countries[3,4] has transformed SCD into a chronic degenerative disease in adults with increasing morbidity due to complications in multiple organs, all contributing to the reduction in life expectancy by 20 to 30 years compared to the general population.[5,6]

This chapter presents the diagnosis and natural history of SCD and describes overall clinical management as well as specific management by organ complications. Clinical interventions are founded on an understanding of underlying pathophysiologic processes. The exigency of living with a painful, life-threatening chronic disease in an ethnically diverse society adds complexity to the psychosocial aspects of this illness. A comprehensive management approach directed at preventing pain crises, chronic organ damage, and early mortality while effectively managing acute complications is recommended. For a full discussion of the history and molecular pathology of this disease, refer to Chapter 42. Normal Hb synthesis, structure, and function are described in Chapter 34, and the thalassemias are described in depth in Chapter 41.

GENETIC EPIDEMIOLOGY OF THE SICKLE GENE

Heterozygotes for the sickle gene (sickle trait or HbAS) who are generally asymptomatic have a substantial survival advantage in malaria-endemic environments. HbAS individuals are not only protected from effects of severe *Plasmodium falciparum* malaria but also from consequences of malaria infection, including malnutrition and bacterial infections,[7] a result of which is the very high population frequencies of 10% to 20% in historically malaria-endemic regions.[8] However, with the increased premature death rate of patients with SCD, the sickle cell gene represents a balanced polymorphism.[9] Early genetic studies based on β^S haplotypes generated by restriction fragment length polymorphisms in the globin-gene cluster on chromosome 11, hypothesized that the β^S mutation arose and amplified separately in at least four African locations between 2000 and 4000 years ago and once in the Middle East or India.[10] Recent studies based on whole-genome sequence data and phased single nucleotide polymorphisms (SNPs), however, suggest that *rs334* arose once approximately 7300 years ago in West Africa on HAP1 haplotype from which the other haplotypes were then derived.[11] Another study based on sequencing of the β-globin gene (*HBB*) cluster supported a single origin of *rs334* but estimated an earlier origin about 22,000 years ago.[12]

VARIANT SICKLE CELL SYNDROMES

The sickle cell syndromes that result from inheritance of the sickle cell gene in simple heterozygosity or in compound heterozygosity with other mutant β-globin genes are sickle cell trait, HbSC disease, and HbSβ-thalassemia. These and other less common compound heterozygosity syndromes are reviewed.

PREVALENCE

The distribution and frequency of the sickle cell gene in geographic regions of the world have been influenced by natural selection and gene transmission via trade routes including the slave trade.[10,13,14] In recent years, further expansion of the distribution of the sickle cell allele resulted from globalization. Among African Americans,[15] the prevalence of sickle cell trait is 8% to 10% among newborns,[16] and in this population, the frequencies of the sickle cell (0.045), HbC (0.015), and β-thalassemia (0.004) genes[16] indicate that there are 4000 to 5000 pregnancies a year at risk for SCD.

Based on data from the Centers for Disease Control and Prevention, there are approximately 100,000 individuals in the United States (US) with SCD.[17] Overall, it is estimated that approximately 1 out of every 365 African American and 1 out of every 16,300 Hispanic American births in the US are affected by SCD.[18] Approximately 3 million people (majority of African descent) and 8% of Black or African American individuals in the United States are sickle carriers.[19] It is worth noting that due to both the presence of the HbS mutation in the Mediterranean region and to population admixture, sickle cell disorders can occur in individuals of European origin who do not report African ancestry.

The burden of this disease in the US is dwarfed by that in the rest of the world, evidenced by an estimated 300 million sickle carriers (~5% of the world's population) globally, with 5.5 million AS births annually.[20] Globally, it is estimated that more than 300,000 children are born with SCA every year, and this burden is expected to increase to 400,000 by 2050 largely due to reductions in infant mortality[21,22]; more than 50% of the births occur in Nigeria, Democratic Republic of Congo, and India.

CLINICAL LABORATORY FEATURES AND DIAGNOSIS

The chronic hemolytic anemia of SCD presents with mild to moderately low Hb and hematocrit (Hct) levels and a reticulocytosis of approximately 3% to 15%. Additional laboratory features of hemolysis include unconjugated hyperbilirubinemia with relative elevations of both indirect (unconjugated) and total bilirubin, elevated lactate dehydrogenase (LDH), and low to absent haptoglobin levels. During vaso-occlusive episodes (VOEs), hemolytic laboratory parameters may become more pronounced with significant elevations in bilirubin, LDH, and reticulocyte counts above steady-state levels in addition to worsening of anemia. Baseline compensatory reticulocytosis in the setting of chronic hemolysis accounts for high or high-normal mean corpuscular volume (MCV). If the age-adjusted MCV is not elevated, the possibility of sickle cell–β-thalassemia, coincident α-thalassemia, or iron deficiency must be considered in the diagnostic work up.

In the peripheral smear (Fig. 43.1), there may be sickled RBC forms, target cells, polychromasia indicative of reticulocytosis, and Howell-Jolly bodies in the setting of functional hyposplenia or asplenia. RBCs are typically normochromic unless there is coexistent thalassemia or iron deficiency. Sickled forms (irreversibly sickled cells [ISCs]) occur in the peripheral smear only in SCD and not in sickle cell trait. In HbSS disease, ISCs predominate, and target cells may be few; in HbSC disease, target cells predominate, and ISCs are rare; in sickle cell–β-thalassemia, ISCs, target cells, and hypochromic microcytic discocytes are prominent.

White blood cell (WBC) counts are higher than normal in HbSS and HbSβ^0-thalassemia disease, particularly in patients under age 10 years. Mean WBC counts tend not to be elevated in HbSC disease or HbSβ^+-thalassemia. Mean platelet counts are elevated in SCA, particularly in patients younger than age 18 years, but are usually normal in those with HbSC disease and HbSβ^+-thalassemia.

Solubility Tests and Hemoglobin Electrophoresis

Solubility test results (e.g., Sickledex) are positive in both SCD and sickle cell trait. All patients require definitive diagnosis with Hb electrophoresis (which separates Hb species according to amino acid composition) (Fig. 43.2) or high-performance liquid chromatography (HPLC).[23] Cellulose acetate electrophoresis at a pH of 8.4 is a standard method of separating HbS from other variants. However, HbS, G, and D have the same electrophoretic mobility with this method. Using citrate agar electrophoresis at pH 6.2, HbS has a different mobility than HbD and HbG, which comigrate with HbA in this system.

Results from electrophoresis or thin-layer isoelectric focusing are similar in HbSS disease and HbSβ^0-thalassemia: nearly all of the Hb consists of HbS. Although differences in the HbF (see Variant Sickle Cell Syndromes) and HbA$_2$ levels may be useful in distinguishing these syndromes, the presence of microcytosis of one parent without sickle cell trait is a more useful indicator of HbSβ^0-thalassemia or HbS–β^+-thalassemia. The diagnosis of HbSC disease is straightforward; nearly equal amounts of HbS and HbC are detected. HbSβ^+-thalassemia and sickle cell trait both have substantial amounts of HbA and HbS; whereas sickle cell trait is associated with neither anemia nor microcytosis and has an HbA fraction more than 50%,[24] sickle cell–β^+-thalassemia is associated with anemia, microcytosis, and an HbA fraction less than HbS, ranging from 5% to 30%.

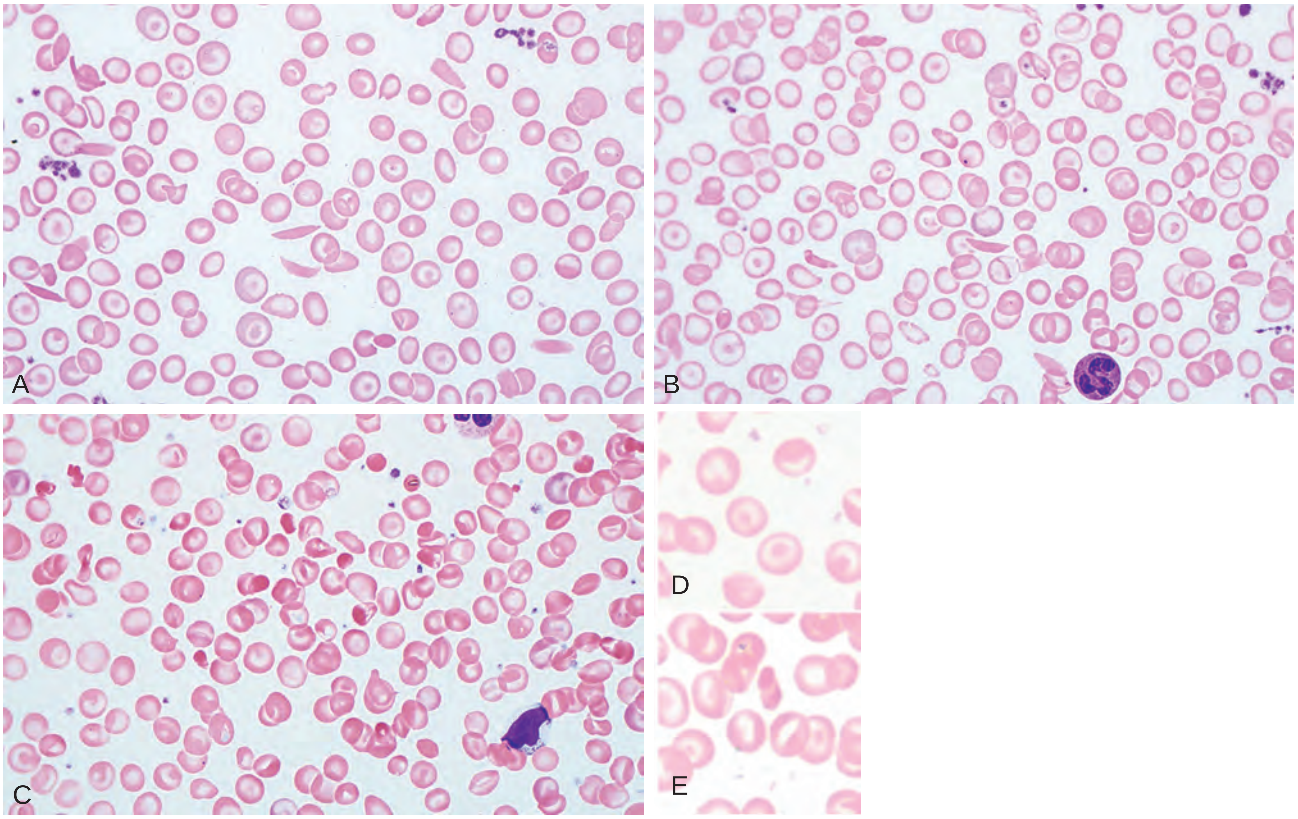

Figure 43.1 SICKLE CELL DISEASE AND HEMOGLOBIN SC PERIPHERAL BLOOD SMEARS. The peripheral smear in sickle cell disease (A) shows sickle cells that are mostly irreversibly sickled and sometimes referred to as "cigar forms." Higher power detail (B) shows a sickle cell *(upper left)*, red blood cell containing a Howell-Jolly body *(middle right)*, and polychromatophilic cell *(lower center)*. These indicate sickle cell anemia and splenic dysfunction but marrow response with reticulocytosis, respectively. A peripheral smear of a patient with HbSC (C) shows no sickled cell, but there are target forms (D) and occasional cells (E) with hemoglobin condensed at each pole of the cell.

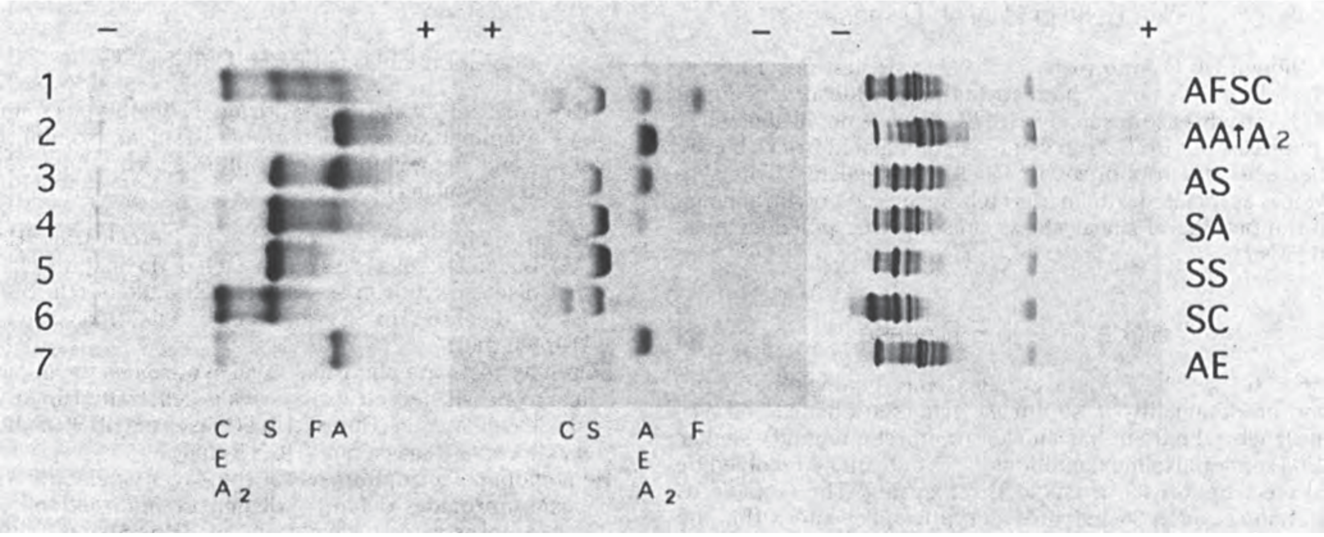

Figure 43.2 COMPARATIVE ANALYSES OF SEVERAL MUTANT HEMOGLOBINS USING ALKALINE ELECTROPHORESIS, ACID ELECTROPHORESIS, AND THIN-LAYER ISOELECTRIC FOCUSING. On the *right* are shown the components of the standard *(top)* and the phenotypes of the other six samples. Their analyses are shown by alkaline hemoglobin electrophoresis in the *left panel*, acid electrophoresis in the *center panel*, and thin-layer isoelectric focusing in the *right panel*. Locations of the various hemoglobin bands are shown below the left and center panels. *A*, Hemoglobin A; *A2*, hemoglobin A2; *C*, hemoglobin C; *E*, hemoglobin E; *F*, hemoglobin F; *S*, hemoglobin S. (*Courtesy M. H. Steinberg.*)

Coinheritance of alpha-thalassemia (silent carrier or trait) is difficult to ascertain from standard hematology and requires DNA sequencing of the alpha-globin gene which can be performed as a send out test to specialized laboratories.

The HbF level is usually slightly to moderately elevated although there is significant variability among patients. The amount of HbF present is a function of the number of reticulocytes that contain HbF, the extent of selective survival of HbF-containing reticulocytes that become mature HbF-containing erythrocytes (F cells), the amount of HbF per F cell, and co-inheritance of HbF genetic variants, including the β^S-haplotypes.[25] The Arab–Indian and Senegal haplotypes are associated with higher levels of HbF than the others.[26] HbF is also influenced by SCD-directed therapies, specifically hydroxyurea (HU), which will be discussed later in this chapter.

Newborn Screening

The use of prophylactic penicillin[27] and the provision of comprehensive medical care during the first 5 years of life have reduced the mortality rate from approximately 25% to less than 3%, thereby underlining the importance of early identification of infants with SCD. Based on its economy and superiority of detection, universal screening of all newborns is preferred over ethnically targeted approaches.[28,29] This screening approach was endorsed by a consensus panel convened by the National Institutes of Health.[28] Since 2008, SCD screening in newborns is mandated in all 50 states of the US and the District of Columbia.[30] Blood samples for testing are obtained by heel stick and spotted onto filter paper for stable transport and subsequent HPLC. It should be noted that HPLC screening in very premature newborns can result in misdiagnosis given that the switch from fetal to adult Hb has not completed and the level of HbS may still be below the threshold for solubility testing and the results may not be valid.

As HbS increases and HbF declines in the first months of life (Fig. 43.3), the clinical manifestations of SCD, including anemia, emerge.[31] ISCs can be seen on the peripheral blood smear (Fig. 43.4) of children with SCA at 3 months of age, and by 4 months of age, moderately severe hemolytic anemia is evident.

Tests used in newborn screening must be capable of distinguishing between HbF, S, A, and C. The Hb distribution pattern is described in descending order according to the quantities detected. Therefore, a newborn with SCA who has predominantly HbF with a small amount of HbS and no HbA is described as having an FS pattern. An FS pattern is obtained also in newborns who have HbSβ°-thalassemia, HbS–hereditary persistence of HbF (HPFH), and HbSD or HbSG (since HbD and HbG have the same electrophoretic mobility as HbS). A newborn with sickle cell trait will have HbF, HbA, and HbS (FAS pattern). The quantity of HbA is greater than that of HbS. If the quantity of HbS exceeds that of HbA, the presumptive diagnosis is HbS/β^+-thalassemia (FSA pattern). It may not be possible to distinguish FAS and FSA patterns in newborns, so DNA-based testing or repeat Hb testing at age 3 to 6 months is recommended. Several alternative, point-of-care approaches are currently under development and a commercially available kit utilizing an antibody-based lateral-flow assay is marketed under the name of Sickle SCAN.[32]

CLINICAL PRESENTATION AND MANAGEMENT

The clinical manifestations of SCD include chronic hemolytic anemia, recurrent VOEs, and chronic end organ damage, particularly of the spleen, bones, brain, kidneys, lungs, skin, and heart. It is important to recognize that chronic organ damage is insidious and all SCD patients have decreased survival, even those with infrequent pain episodes or with a seemingly mild disease phenotype. The pattern of disease manifestation varies among the major genotypes of HbSS, HbSC, and HbSβ-thalassemia but also within the same genotype. Some of this variability is the result of coinherited genetic variants, for example, α-thalassemia or HPFH (refer to the end of this chapter).

This section begins with a brief overview of the natural history of SCD and survival followed by a discussion of disease-modifying therapies and then a discussion of organ-specific complications and their respective management.

Natural History and Life Expectancy

The manifestations of disease begin after the first few months of life as HbF levels decline and HbS levels increase. Certain complications predominate in particular age groups. Between the ages of 1 and 3 years, affected individuals develop splenomegaly and splenic sequestration (Fig. 43.5), pneumonia, and meningitis from *Streptococcus pneumoniae* and other encapsulated organisms because of functional hyposplenism, and hand–foot syndrome (dactylitis); in early childhood, ACS, osteonecrosis, and stroke predominate; in mid childhood, pain crises, osteonecrosis, and ACS are again common presentations; between ages 12 and 20 years, patients may develop strokes, priapism, and recurrent pain episodes.[33]

As patients with SCD age, chronic end organ damage begins to manifest thereby complicating their clinical management and disease course. By the ages of 20 to 30, patients with SCD may develop sickle cell nephropathy with albuminuria, sickle retinopathy, sickle related liver disease, disabling avascular necrosis of multiple joints, recalcitrant leg ulcerations, and chronic pain. Pain becomes the most common complication, frequently acute-on-chronic; chronic pain is usually multifactorial secondary to ongoing inflammation, central and peripheral neural sensitization, and avascular necrosis.[34]

Verbal and motor neurologic deficits secondary to prior overt strokes and neurocognitive deficits are common in adult SCD cohorts. In addition, complications related to SCD treatment such as transfusional iron overload and alloimmunization occur although these may develop in much younger individuals depending on clinical course and transfusion history.

Beyond age 30, patients demonstrate progressive worsening of end organ complications and may also develop age-related medical conditions such as osteoarthritis and diabetes mellitus. Aging patients with SCD are at high risk for developing pulmonary complications including pulmonary hypertension (PH) related to the underlying pathophysiology of the disease and/or recurrent thromboembolic events, termed chronic thromboembolic pulmonary hypertension (CTEPH). PH affects 6% to 11% of SCD adults and is a leading cause of morbidity and early mortality.[35] Other pulmonary complications include reductions in vital capacity from pulmonary fibrosis due to parenchymal damage, manifested as impaired exercise tolerance, worsening heart failure, and impaired pulmonary function with evidence of restrictive physiology. Sickle cell chronic lung disease is a term used for these pulmonary lung complications but should be discouraged as these pulmonary complications are not unique to SCD.[36] Exercise intolerance can also arise from associated high output and left ventricular heart failure in the setting of chronic anemia.[37]

Albuminuria and Stage I–II chronic kidney disease (CKD) may progress to late-stage renal disease and overt renal failure requiring hemodialysis (HD) in approximately 4% to 12% of patients with SCD.[38] A multidisciplinary approach integrating the expertise of hematology, cardiology, pulmonology, and nephrology is necessary in the medically complicated aging patient with SCD.

Life expectancy for individuals with SCD is decreased as compared to the general population without SCD, although over the past 30 years this has dramatically improved for patients in Western countries with access to comprehensive medical care. In 1973, Diggs[39] reported that the mean survival was 14.3 years of age. In 1994, Platt et al.[40] reported that life expectancy was 42 years for men and 48 years for women with SCD (Fig. 43.6). Early improvements in survival trends were most likely the result of improved general medical care, including prophylactic penicillin therapy and vaccination against *S. pneumoniae*.[27]

In a cohort of 542 adult patients with SCD followed at tertiary care medical centers in the Southeastern United States from 2002, the observed median survival for patients with HbSS and HbSβ^0 genotypes was 58 years, and median survival for HbSC and HbSβ$^+$ genotypes was 66 years.[6] In a 2016 study involving 712 patients followed at King's College Hospital in London, the median survival for patients with HbSS and HbSβ^0 disease was 67 years.[5] This improved survival was attributed to expert care delivered at a specialized hematology clinic, comprehensive multidisciplinary inpatient management, involvement of specialists, availability of RBC exchange, and an established program to facilitate the safe and effective transition from pediatric to adult care. It is important to note that disease-modifying agents, such as HU, can improve survival in SCD cohorts. Because of its overall safety profile and efficacy, guidelines from both the US and UK recommend HU as standard care treatment for all individuals with HbSS and HbS/HbSβ^0-thalassemia regardless of clinical severity as prevention/reduction of sickle-related complications.[41–43] HU was US Food and Drug Administration (FDA) approved for use in adults in 1998 and in children in 2017.

Predictors of Disease Severity

The ability to predict clinical course allows for more rational tailoring of therapy to individual patients (e.g., selection of patients for high-risk but effective options such as stem cell transplant). While some clear predictors have been identified, the challenge is to predict "severe disease" before end organ complications manifest as reflected by commonly used clinical, laboratory, and imaging markers.[44] Higher baseline HbF levels and the coinheritance of an α-thalassemia trait have been identified as favorable disease modifiers in multiple studies (Table 43.1).[49–51] The severity of chronic anemia is of considerable predictive value. Patients with more severe anemia are more likely to develop infarctive and

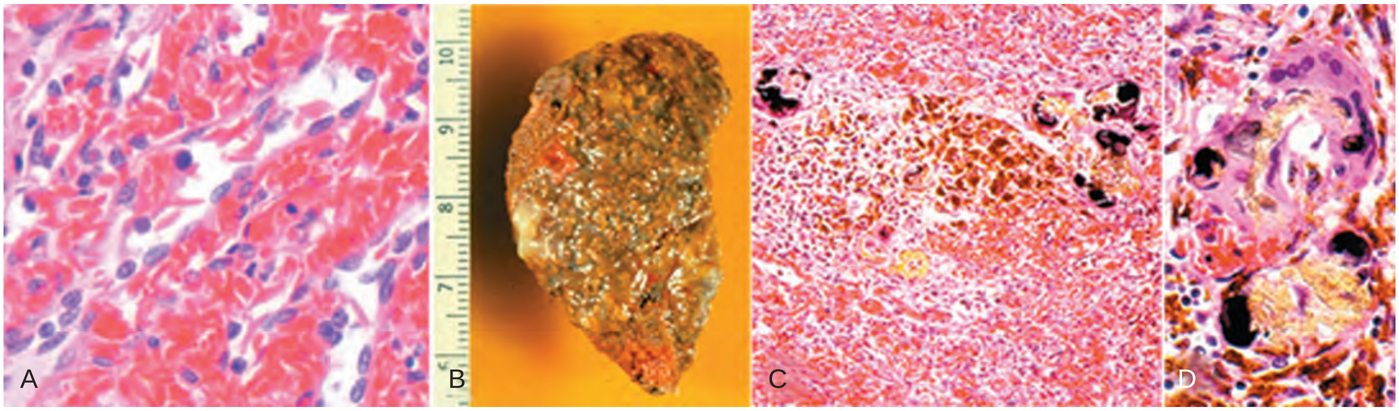

Figure 43.5 THE SPLEEN IN SICKLE CELL DISEASE. Histologic section (A) of the splenic red pulp shows engorgement of the splenic cords with sickled cells. In infants, excessive pooling in cords can lead to a splenic sequestration crisis. Later in life, the spleen undergoes autoinfarction. The gross pathology (B) shows a tiny 4.5-cm spleen with rough external surface caused by scarring from repeated infarcts. Histologic section reveals classic Gamna-Gandy bodies (C and D) also caused by repeated infarction. These are composed of hemosiderin-laden macrophages, calcium deposits, and foreign body giant cells.

hemorrhagic stroke,[52] to have glomerular dysfunction,[53,54] and are more likely to give birth to low-birthweight babies.[55,56] Conversely, they have fewer episodes of ACS[57] and after age 20 years, a lower mortality rate.[57] Progressive anemia from renal, endocrine deficiency or a decrease in bone marrow function from vaso-occlusion is associated with early death.[58,59]

An early study aimed at identifying risk factors for mortality in adults utilizing algorithmic modeling in a cohort of 964 individuals with SCD identified ACS, renal failure, baseline white blood count greater than 15,000/μL, and a HbF of 8.6% or less to be associated with early death.[40]

Risk factors for death in two contemporary adult SCD cohorts treated at tertiary medical centers included high frequency of hospitalizations, presence of iron overload, elevated tricuspid regurgitant jet velocity (TRJV) on transthoracic echocardiography (>2.5 m/s), history of any cerebrovascular event, lower estimated GFR, and at least one pain episode in the preceding year.[5,6] Laboratory findings including low hemoglobin, high baseline WBC count, low baseline HbF, elevated LDH, high C-reactive protein (CRP), and elevated NT-proBNP were also predictive of early mortality in these patient cohorts. A more recent approach utilized novel machine learning methods to select variables of importance without any pre-conceived assumptions leading to the selection of nine key parameters and a simple risk score that reflects the summation of cardio-pulmonary, renal, and liver end-organ damage. An online tool was created to calculate this individual risk score and predicted survival in SCD patients.[60]

In genome-wide association studies (GWAS), millions of genetic variants, typically SNPs, are queried for possible association with clinical subphenotype in patients with SCD. GWAS have been employed in SCD to study the genetic associations of HbF, bilirubin, cholelithiasis, hemolysis, HbA2 level, tricuspid regurgitation velocity, stroke, and systemic blood pressure.[61] The *UGT1A1* gene promoter variant which underlies Gilbert syndrome is a genetic modifier of bilirubin levels and prevalence of gallstones in patients with SCD. Bilirubin levels increase with hemolysis, and the intensity of hemolytic anemia is a marker of severity in SCD. Another validated result in SCD populations as a result of GWAS is the association of an SNP in *NPRL3* with hemolysis.[61] A number of other genetic polymorphisms may be relevant to disease severity and phenotype. However, the number of validated markers is small and at a stage that cannot be used to guide decision-making.[50,62]

Principles of Clinical Management

The pillars of therapy are disease modification (prevention of crises, complications, chronic end organ damage, and early mortality) and compassionate, prompt, effective, and safe relief of acute crises, including pain episodes.[63] Therefore, outpatient clinic management is mostly directed at initiating measures to prevent pain crises, prevent organ complications, and improve survival. This effort should include identification of existing organ complications and initiation of measures to prevent further deterioration. Outpatient management can thus be divided into baseline evaluations, basic treatment or disease modification, and additional treatment dictated by the organ complications that are identified. The suggested treatments are based on current understanding of SCD pathophysiology. As shown in Fig. 43.7, some treatments address only one aspect of pathophysiology, but others may have a broader impact.

Baseline Evaluations

Baseline blood, urine, and other evaluations are directed at quantifying chronic hemolytic anemia and organ-specific complications (Table 43.2). They also provide baseline parameters that can be followed to assess response to therapeutic interventions.

In pediatric patients with HbSS disease and HbSβ°-thalassemia, at least annual assessment of cerebral blood flow in the internal carotid artery and the middle or anterior cerebral artery using transcranial Doppler ultrasonography (TCD) is recommended. TCD screening is initiated at age 2; it is not recommended in patients greater than 16 years of age. This evaluation is a validated predictor of stroke risk. Primary prevention with chronic transfusion to maintain the maximum hemoglobin S level at less than 30% is effective in such patients.[64] Children with evidence of cognitive or neurologic dysfunction (e.g., poor school performance, concerns expressed by family members) should be screened for silent infarcts using magnetic resonance imaging (MRI). In adults, MRI or magnetic resonance angiography (MRA) of the brain can be used instead of TCD[65] to assess thrombotic or hemorrhagic stroke risk, especially in those with a history of prior stroke or seizure.

The recognition of cardiopulmonary complications as a cause of early mortality in SCD warrants evaluation for this condition with either echocardiogram or brain natriuretic peptide (BNP) levels. In adult asymptomatic patients, baseline transthoracic echocardiogram should be considered for screening. If PH is suspected based on clinical symptoms or echocardiogram findings including borderline or elevated TRJV in an adult, a referral to a pulmonologist with consideration of right-heart catheterization is recommended.

The 2019 American Society of Hematology (ASH) Guidelines for Sickle Cell Disease advise aggressive blood pressure management in patients with a history of pre-hypertension or hypertension. Early treatment of systemic hypertension is critical; mild elevations in blood pressure are associated with an increased risk of overt stroke and silent cerebral infarct in patients with SCD.[66] The ASH 2019 Guidelines strongly recommended a blood pressure goal of less than 130/80 to prevent progression of renal damage which results in chronic insufficiency and in later stages, renal failure.

Urinalysis and metabolic panel to screen for albuminuria and CKD should be assessed at baseline and at least annually. The

National Heart, Lung, and Blood Institute (NHLBI) 2014 expert panel report stated that screening for albuminuria should occur annually beginning at 10 years of age for patients with SCD. In select patients with albuminuria, the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) may be considered although caution must be exercised during initiation of therapy, particularly in the setting of concomitant renal insufficiency. While prospective data is limited, there is increasing evidence that early initiation of ACE inhibitors or ARB therapy may prevent progression of albuminuria and medical renal disease in patients with SCD.

Retinal evaluation is begun at age 10 and continued on an annual basis. More frequent retinal evaluations and ophthalmologic interventions are necessary if proliferative sickle cell retinopathy is noted.

In chronically transfused patients, ferritin levels should be serially measured at least every 3 to 4 months and must be drawn in the steady state (i.e., in the absence of acute pain crisis or VOC).

Chelation therapy is typically started after two years of transfusion in chronically transfused individuals, or after approximately 120 mL of transfused RBCs per kilogram, and when the serum ferritin exceeds at least 1000 μg/L or the liver iron concentration (LIC) is greater than 7 mg/g dry weight.[67] Quantification of tissue iron stores should be undertaken to determine optimal timing of iron chelation therapy. At specialized centers, both hepatic and cardiac iron burden can be quantified non-invasively with MRI; although liver biopsy to assess LIC remains an alternative it is less desirable method. Patients receiving iron chelation should have serial iron indices and ferritin levels performed regularly and chelation regimen adjusted as needed.

Basic Management and Disease Modification

Sufficient evidence suggests that a number of treatments should be considered in all patients. These treatments have been demonstrated to decrease symptoms and complications, increase survival, or both (Table 43.3) (disease modification). There are other treatments for which there are sufficient scientific grounds or clinical data to suggest a potential impact on disease natural history. However, there is presently insufficient clinical data to make firm recommendations (see Fig. 43.7 and Table 43.3). Although treatments such as vaccination and penicillin prophylaxis do not directly affect the sickling process or vasculopathy, they have had an impact on survival and therefore are included under the umbrella of disease-modifying therapies.

Therapeutic options are further discussed in the sections describing organ-specific complications.

Nutritional Supplementation

Chronic hemolysis results in increased utilization of folic acid stores. Megaloblastic crises from folic acid deficiency have been reported.[68,69] Pediatric patients with SCD have higher homocysteine levels than age-matched control African American patients.[70] Folic acid, 1 mg/day orally, is administered as a standard of care.[71] Vitamin B_{12} deficiency can also be seen in patients with SCD. Folate replacement can mask and possibly exacerbate vitamin B_{12} deficiency.[72]

A growing body of research indicates that sickle cell patients have multiple mineral and vitamin deficiencies, including zinc, vitamin C, vitamin E, acetylcysteine, calcium, vitamin D, and vitamin A.[73] Fifty percent of children with SCD have evidence of osteoporosis or osteopenia that is associated with inadequate calcium and vitamin D intake.[74–76] Recently, zinc supplementation in a prospective trial documented significant improvement in linear growth and weight gain in children with SCD.[77] Therefore daily supplementation with a multivitamin without iron may be of value, and in pediatric and adult individuals with vitamin D deficiency (which is often severe[78]), vitamin D replacement therapy is warranted.

Despite increased intestinal absorption of iron in SCD, the combination of nutritional deficiency and urinary iron losses results in iron deficiency in 20% of children with SCD.[79] The diagnosis of iron deficiency may be obscured by the elevated serum iron levels associated with chronic hemolysis, necessitating the detection of a low serum ferritin level or an elevated serum transferrin level for the diagnosis. The treatment of iron deficiency in children must be balanced with the potential risk for transfusion iron overload in the setting of RBC transfusions. In contrast, there are also reports that suggest iron-restricted erythropoiesis may reduce the frequency of VOCs due to the reduction of intracellular hemoglobin S concentration[80] but to date, there have been no clinical trials to test this hypothesis.

Vaccination and Penicillin Prophylaxis

Children with SCD should be immunized against *Neisseria meningitidis*, *S. pneumoniae*, *Haemophilus influenzae* type B, seasonal influenza, and hepatitis B in addition to all other standard vaccinations.[81] Vaccination decreases the incidence of invasive pneumococcal disease in children with SCD.[26,82] In the United States, a 13-valent pneumococcal conjugate vaccine (PCV13) and a 23-valent pneumococcal polysaccharide vaccine (PPSV23) are available. All children with SCD should be immunized with both PCV13 and PPSV23 as per American Academy of Pediatrics (AAP) guidelines. In adults, the Pneumovax should be re-administered every 5 years.

Penicillin prophylaxis begins at 3 months. The dose from age 3 months to 3 years is 125 mg penicillin V orally twice daily, and at age 3 years this should be increased to 250 mg twice daily until age 5 years. After the age of 5 years, penicillin prophylaxis can be stopped unless the patient has been splenectomized or there is a previous history of pneumococcal sepsis.[81,81a] Randomized, double-blind, placebo-controlled studies of prophylactic penicillin beginning in infancy, including the prophylactic penicillin or placebo study (PROPS), have found that this therapy reduced the incidence of *S. pneumoniae* bacteremia by 84% in children younger than 3 years.[26,82] A randomized, double-blind, placebo-controlled study, the PROPS II study, concluded that it is safe to stop prophylactic penicillin therapy at age 5 years in children who have not had prior severe pneumococcal infection or splenectomy and are receiving regular follow up care.[83] However, the power of the study was restricted by the limited number of *S. pneumoniae* systemic infection events. The decision of whether to continue antibiotic prophylaxis after age 5 must be made on a case-by-case basis. In an analysis of a patient population receiving penicillin prophylaxis and the Pneumovax, the rate of severe *S. pneumoniae* infections was 2.4 per 100 patient-years. This was favorable compared with the historic pre-penicillin prophylaxis rate of 3.2 to 6.9 per 100 patient-years.[84] These measures reduce risk but do not remove it. The risk of recurrent *S. pneumoniae* sepsis and death in patients who have had previous sepsis is significantly increased; all patients with a history of pneumococcal sepsis should remain on penicillin prophylaxis indefinitely and are not candidates for outpatient management of febrile episodes.[85] Parents must be aggressively counseled to seek medical attention for all febrile events.

Hydroxyurea and Fetal Hemoglobin Reactivation

The level of HbF in erythrocytes plays a critical role in determining patient outcomes. Individuals who have SCD and HPFH have 70% HbS in their RBCs but are neither anemic nor symptomatic.[86] The uniform distribution of HbF among their RBCs interferes with HbS polymerization, increases its solubility, and prevents RBC sickling.[43,87] Even at lower levels of HbF seen in patients without HPFH, crisis rate and mortality are inversely proportional to HbF level.[51]

HU is an inhibitor of ribonucleotide reductase and a cytotoxic agent that elevates HbF levels via unknown pathways. Long-term use of HU in non-randomized studies has been associated with increased survival in patients with HbSS disease.[88]

A double-blind, placebo-controlled, intention-to-treat multicenter study of HU as treatment of pain crisis in SCD found that HU produced definite hematologic changes. HU was initiated at 15 mg/kg/day and escalated to 0.30 mg/kg/day as tolerated and to maintain an absolute neutrophil count no lower than $2000 \times 10^9 L^{-1}$. There were significant increases in the levels of Hb, HbF, F cells, F reticulocytes, packed cell volume (PCV), and MCV and declines in the mean level of leukocytes, polymorphonuclear leukocytes, reticulocytes, and dense sickle cells (Table 43.4).[89] The significant clinical changes were decreased rate of acute painful episodes, longer interval to first and second acute painful episodes, fewer episodes of ACS, and diminished numbers of PRBC units transfused (Table 43.5).[90] In follow-up analysis, higher pre- or post-treatment HbF levels were associated with a reduction in mortality rate although no

significant changes were observed in the incidence of stroke, hepatic sequestration, or death in the initial study.[58] No short-term toxicity caused by HU was observed. One child born to a patient taking HU and two born to partners of patients taking HU were normal at birth. Although follow-up analyses suggest the importance of HbF to better outcomes, it is possible that some HU-induced changes in sickle cell erythrocytes, such as increased water content and decreased HbS concentration,[91] may be independent of HbF.

In the original study, only patients with two or more pain crises per year requiring hospitalization were eligible. However, other at-risk patients should be considered for HU therapy. These include patients with evidence of chronic organ damage, patients with severe anemia (unless the reticulocyte count is $<250{,}000\ \mu L^{-1}$, in which case consider erythropoietin [EPO] deficiency from renal damage or bone marrow suppression that may require alternative treatment), and patients with indications for chronic transfusion but who have alloantibodies. After obtaining the baseline evaluations per Table 43.2, HU is usually started at 500 to 1000 mg/day with monitoring of the CBC every 4 to 8 weeks to ensure that neutropenia (absolute neutrophil count $<2 \times 10^9\ L^{-1}$) is not produced. Lower doses may be required in patients with renal insufficiency and/or relative reticulocytopenia. The dose may be increased to a stable maximum HbF response or neutropenia, but the majority of patients receive between 500 and 2000 mg/day. Response is defined by clinical symptoms, by a persistent and significant (>0.5 g/dL) increase in total Hb or HbF, and a decrease in LDH. These improvements in symptomatology and hematologic indices may require at least 3 to 4 months of therapy but can be seen as soon as week 6 of treatment.

In studies of HU as a therapy for children with SCD, the drug was well tolerated and produced favorable hematologic changes similar to those seen in the adult population.[92] In approximately 10% of the children treated, the increase in HbF was less than 2%. Baseline HbF levels, baseline total Hb levels, and compliance were associated with the final HbF level.[93] Other studies in children have documented a decrease in the number of days of hospitalization and suggest a decreased incidence of vaso-occlusive crises (VOCs).[94] The favorable changes in hematologic indices suggest that HU therapy might be an alternative to blood transfusions for the prevention of recurrent stroke in children with SCD.[95,96] HU therapy appears to lower transcranial Doppler velocities in children with SCD.[97] Studies in the United States and in Belgium support the potential role of HU in the prevention of cerebrovascular accidents (CVAs).[96,98,99] HU was found to improve, but not correct, the abnormal cerebral oxygen saturation associated with SCD.[100] A persistent concern pertaining to the use of HU in SCD is its putative leukemogenic effect. This concern derives from reports on HU treatment of myeloproliferative diseases, conditions associated with an inherent propensity for leukemic conversion. Although the use of HU combined with 32 P or alkylating agents is associated with increased leukemic conversion in patients with myeloproliferative disease,[101] reports claiming a leukemogenic effect for HU alone in polycythemia vera either lacked control subjects[102] or were not designed to assess this issue.[103] In children with the nonmalignant underlying condition of erythrocytosis secondary to inoperable cyanotic congenital heart disease, no leukemic conversion was observed.[104]

Alternatives to Hydroxyurea for Fetal Hemoglobin Induction

Alternatives to HU for pharmacologic induction of HbF that have been studied in clinical trials include the methyltransferase inhibitor 5-aza-2-deoxycytidine (decitabine) and histone deacetylase inhibitors.[105] These classes of agents act on chromatin processes that regulate gene transcription.[106]

The methyltransferase inhibitors 5-azacytidine and 5-aza-2′-deoxycytidine have produced the largest increases in HbF of any of the pharmacologic reactivators of HbF that have been tested.[107,108] Responding patients included those who did not respond to HU, consistent with a different mechanism of action. Although improvements in a number of surrogate clinical endpoints have been demonstrated, larger studies to confirm safety and clinical effectiveness with chronic use are required. In the United States, 5-azacytidine and decitabine have been approved by the FDA for the treatment of myelodysplastic syndrome (MDS). Decitabine, an analogue of 5-azacytidine, is also a potent DNA methyltransferase inhibitor and has a more favorable safety profile but decitabine is rapidly deaminated and inactivated by cytosine deaminase, if taken orally. To overcome this limitation, a clinical study combining decitabine and tetrahydrouridine (THU), a cytosine deaminase inhibitor, as a therapeutic strategy for inducing HbF, is currently under evaluation for efficacy in a phase II study, following promising results in a phase I study.[109] The efficacy of the class of agents known as histone deacetylase inhibitors in HbF reactivation has been reviewed and includes Panobinostat, a pan histone deacetylase inhibitor.[108,110,111] Other classes of drugs being evaluated for potential HbF reactivation are the “imid” class of drugs (analogues of thalidomide such as pomalidomide) and inhibitors of lysine demethylase (LSD1/KDM1A).[112]

Voxelotor

Voxelotor was approved by the FDA in November 2019 for the treatment of SCD in patients aged 12 years and older. Voxelotor inhibits sickling by preferentially binding to the high-oxygen affinity, nonpolymerizing R conformation of hemoglobin, thereby reducing the concentration of the polymerizing T conformation and stabilizing the oxygenated hemoglobin state.[113] Although there is a modest increase in hemoglobin that is accompanied by decreased markers of hemolysis, suggestive of reduced sickling, to date, there is no evidence that it reduces frequency of pain crises, prevents organ damage, or prolongs survival. Approval was based on the surrogate endpoint of Hb increase of at least 1.0 g/dL or greater from baseline at Week 24 of treatment. There is concern that Hb molecules with the drug bound are in a conformation that delivers very little oxygen, i.e., drug-induced reduction of functional oxygen content (FOC), which is particularly detrimental in a disease characterized by decreased oxygen delivery.[114] Hopefully, these concerns will be addressed in current multicenter phase III clinical studies in both adults and children.

It is important to note that voxelotor interferes with determination of Hb fractions as per HPLC and may make routine HbF monitoring in patients receiving concomitant HU challenging.[115,116] As such, it is recommended that baseline HPLC be obtained in patients receiving HU prior to initiating voxelotor therapy.

Crizanlizumab

Crizanlizumab-tmca was approved by the FDA in November 2019, and represents the first in its class approved for reducing the frequency of VOCs in adult and pediatric patients aged 16 years and older.[117] Crizanlizumab is a humanized monoclonal antibody to P-selectin and its mechanism of action is to block the abnormal adhesion of activated erythrocytes, neutrophils, and platelets to the endothelium. A phase II, multicenter, randomized, placebo controlled double-blind study of crizanlizumab with or without HU (SUSTAIN study) (ClinicalTrials.gov Identifier: NCT01895361) demonstrated that patients on the treatment arm had a significantly lower rate of sickle-related pain crises compared to placebo with a lower incidence of adverse events.[118]

The primary efficacy endpoint in the SUSTAIN trial was the annualized rate of VOC episodes, which was a composite endpoint comprised of pain crisis, ACS, hepatic sequestration, splenic sequestration, and priapism. Post hoc analyses showed that more patients were VOC event-free in the crizanlizumab arm than in the placebo arm, and that crizanlizumab also significantly increased time-to-first VOC compared to placebo.[119] A phase 3 interventional, multicenter, randomized, double-blind clinical trial is ongoing to assess safety and efficacy of crizanlizumab with or without HU in patients with SCD and history of VOC (ClinicalTrials.gov Identifier: NCT03814716). Infusion-related reactions were observed in 2 (3%) patients treated with the 5 mg/kg dose level in the SUSTAIN trial. Crizanlizumab can induce pseudothrombocytopenia on automated platelet counts when ethylenediaminetetraacetic acid (EDTA) tubes are implemented.[120]

L-Glutamine

L-glutamine (an amino acid) taken twice daily in powder form was FDA-approved for preventing acute VOC events in children aged 5 years and older and adults with SCD in July 2017.[121]

In a phase III study, L-glutamine demonstrated a 25% reduction in the median number of pain crisis, 30% less hospitalizations, and reduced acute chest episodes in children and adults with SCD with or without HU over a 48-week period.[122] Interpretation of the results is complicated by high dropout rates that were observed with approximately 36% in the L-glutamine arm and 24% in placebo arm discontinuing the study early. It should be noted that one of the exclusion criteria for the study was renal insufficiency, a concern for SCD patients, many of whom have renal impairment (see box on Role of Novel Therapeutic Agents in Sickle Cell Disease).[123]

ROLE OF NOVEL THERAPEUTIC AGENTS IN SICKLE CELL DISEASE

In 2017, L-glutamine (Endari), and in 2019, voxelotor and crizanlizumab were approved by the US FDA for the treatment of SCD. Voxelotor increases Hb levels whereas Endari and crizanlizumab were demonstrated to reduce the frequency of VOC events, including pain crises, as compared to placebo. There are no consensus-based algorithms to guide hematologists on how these drugs should be implemented in the clinical setting. Notably, all three drugs can be used concomitantly with hydroxyurea therapy and the majority of patients in the pivotal trials had been stabilized on hydroxyurea therapy prior to enrollment. So, when do we initiate these new agents in the management of SCD?

HU is an efficacious anti-sickling agent and has an established safety profile and therapeutic benefits for greater 30 years. HU is now considered standard of care for all individuals with sickle cell anemia, regardless of severity of disease, in both adults and children. Thus, before considering these newer agents, a trial of hydroxyurea therapy should initially be considered and dosage titrated for maximal benefit. Consider adding second-line agents only when response to HU is minimal despite stabilization on maximum tolerated dose (MTD). Choice of second agents depends on an individual's clinical phenotype and what we are trying to achieve—improving baseline Hb levels or reducing the frequency of acute pain episodes.

If the main aim is to improve oxygen-carrying capacity, i.e., hemoglobin, consider supplementing HU with an ESA but some patients may be resistant to a subcutaneous route of administration. Long-term follow-up from final analysis of 72-week voxelotor treatment data is not yet available. Voxelotor can be considered in combination with HU, and also in patients intolerant to hydroxyurea secondary to significant cytopenias or adverse effects. There is some concern, however, that Hb molecules bound with voxelotor are in a conformation that delivers very little oxygen, which can be especially detrimental in a disease characterized by decreased oxygen delivery. Hence, special consideration must be paid to patients with prior stroke and silent cerebral infarcts. It should also be noted that HbS-voxelotor complexes, while useful in monitoring voxelotor therapy, cause interference with determination of HbS and HbF fractions in routine HPLC laboratory techniques.

HU has a proven efficacy in reducing frequency of VOCs and also ACS events, but some patients continue to experience recurrent acute pain episodes while on a MTD of HU. In such patients, crizanlizumab or Endari can be considered in addition to hydroxyurea therapy. While no improvements in baseline hemoglobin or reductions in hemolytic parameters can be anticipated based on the mechanism of the drug, a secondary effect in reduction of VOCs will be stabilization of patient's Hb as VOC events are often accompanied by a drop in Hb. Patients initiating crizanlizumab need to be closely monitored for infusion-related reactions during the initiation of drug. As L-glutamine is an amino acid, one should be cautious in its use among SCD patients in whom renal and hepatic dysfunction are not uncommon.

Stem Cell Transplantation

At this time, allogeneic hematopoietic stem cell transplantation (HSCT) from an HLA-matched sibling donor (MSD) remains the only curative option for SCD, and improvements in conditioning have made this approach feasible in both pediatric and adult populations.[124] Between 1986 and 2013, 1000 SCD patients received HLA-identical MSD HSCTs; the outcomes were excellent with 93% overall survival.[125] Eighty-seven percent of the patients received myeloablative chemotherapy and the rest (13%), mainly adults, received reduced intensity chemotherapy. It is important to note that patients 16 years or older had worse overall survival (81% vs. 95% $P = 001$) and a higher probability of graft-versus-host disease (GVHD)-free survival (77% vs. 86% $P = 001$). As patients can be cured of their SCD without complete replacement of their bone marrow, siblings with sickle cell trait are acceptable as donors as stable mixed hemopoietic chimerism after BMT can be achieved.[126]

Although myeloablative conditioning has achieved high rates of overall and event-free survival, the conditioning is too toxic for adult patients with pre-existing organ dysfunction. Reversal of the sickle hematology without complete replacement of the patient's bone marrow led to the development of less intense conditioning regimens expanding allogeneic transplantation in adult patients[127,128] who otherwise would not be able to tolerate intense myeloablative conditioning. Donors can be HbAA or HbAS, and in order to reverse the sickle hematological genotype, myeloid donor chimerism must exceed 20%.[129] Recent data reported at least 95% cure in 234 children and young adults (<30 years of age) with SCA who received HSCT from an MSD, with no increase in mortality compared to the disease itself and with a better quality of life. The data also demonstrated that myeloablative HSCT can be a safe option for patients less than 15 years old if an MSD is available unless there is a clear and strong recommendation not to undergo transplant.[130,131]

However, in the US, less than 15% of patients with SCD have HLA-matched siblings as donors, but a promising alternative donor source is haplo-identical family members. Studies are now underway in several centers to find a balance of a conditioning regimen that provides adequate immunosuppression without rejection and minimal GVHD.[132] Other sources of hematopoietic stem cells (HSCs) include related umbilical cord blood[133] and matched unrelated donors, the latter source of HSCs as an approach is limited by the probability of finding suitable donors for African and African American populations as per the National Marrow Donor Program. HLA-haploidentical HSCT following reduced-intensity conditioning has been reported to show promising results with prolonged and stable engraftment, but rejection remains a major obstacle as also reported for umbilical cord blood as donor source.[134–138]

The issue of the cost-effectiveness of bone marrow transplantation (BMT) gains perspective from the comparative costs in the United States of $150,000 to $200,000 for an uncomplicated BMT versus up to $112,000 annually for conventional medical care of a chronically transfused, iron-overloaded patient.[139]

Transfusion Therapy

Transfusions in SCD improve the oxygen-carrying capacity of blood and concomitantly dilute circulating sickled erythrocytes to improve microvascular circulation; they also suppress endogenous production of RBCs containing HbS.[140,141]

Blood transfusions as a therapeutic option are used in both the acute and chronic setting. Apart from chronic RBC transfusion for stroke prevention or treatment in children, its use in many other medical situations, such as prevention of recurrent acute pain, priapism, leg ulcers, renal dysfunction, and PH, remains pragmatic based on observations and clinical experience.[141,142]

The two main approaches to transfusion in SCD are simple transfusion and exchange transfusion. These transfusions can be administered in an acute/episodic fashion or on a chronic basis. Therefore, transfusion therapy in SCD is of the following types: episodic simple, episodic partial exchange, or chronic partial exchange. Exchange transfusion can also be manual or automated. In both simple and exchange transfusion, the target Hb level is 10 to 11 g/dL (hematocrit, 30%).[143,144] Transfusing to a higher Hb or hematocrit level is avoided because a hematocrit level greater than 30% is associated with hyperviscosity if there is a substantial proportion of HbS in the blood. The aim of chronic transfusion (simple or exchange) is to maintain a relatively low concentration of HbS. The HbS% target will vary according to indication, HbS% of less than 30% for primary or secondary stroke prevention but when prescribed for other indications (e.g., recalcitrant leg ulceration), a relatively higher concentration of HbS% less than 40% to 50% may suffice. In partial-exchange transfusion, a proportion of the patient's RBCs are removed before transfusion of normal donor RBCs; this can be done manually through phlebotomy followed by transfusion or concurrently using an automated device. In patients who need chronic transfusions, partial exchange is recommended because of the reduced iron burden of this approach. Partial exchange is also indicated if the baseline Hb level is more than 10 g/dL. Simple transfusion in this instance risks exacerbating the clinical condition through increased viscosity. For critical illness, exchange transfusion is also preferred. Although the target HbS level should be less than 30% in exchange transfusion, decreasing HbS levels to less than 50% may suffice depending on the severity of the complication being treated.

The volumes required for simple and exchange transfusions (Table 43.6) are particularly important for transfusing children. For normal-size adults, the general rule is that each unit of RBCs infused should approximately increase the Hb level by 1 g/dL.[142]

Episodic simple transfusion should be considered for blood volume replacement in aplastic crisis and splenic sequestration crises and for protection when there is a more than 20% decrease in Hb from baseline from severe illness such as septicemia, severe VOCs, or Hb levels of less than 5 g/dL. Episodic simple or exchange transfusion should be considered for ACS, multi-organ failure, priapism, and preoperatively. The choice of simple versus exchange transfusion is determined by the pre-transfusion total Hb level and the severity of the illness.

In the preoperative setting, there is randomized data to support the use of preoperative transfusion to decrease the risk of complications, including ACS.[145,146] Preoperative transfusions can be categorized as follows. (1) Top-up transfusions to a target Hb level of 10 g/dL. This is an appropriate intervention for patients with baseline Hb between 6.5 and 9 g/dL undergoing low- or medium-risk surgeries (e.g., cholecystectomy, joint replacement). (2) Partial exchange transfusion to achieve a target Hb level of 10 g/dL with an estimated HbS percentage of less than 60%. This is an appropriate intervention for patients with baseline Hb levels of greater than 9.5 g/dL undergoing low- or medium-risk surgeries as per above. (3) Exchange transfusion to achieve a target Hb level of 10 g/dL with an estimated HbS percentage of less than 30%. This procedure should be considered for patients with SCD undergoing high-risk surgeries (e.g., cardiothoracic surgery). In short, surgery, even low- or medium-risk surgery, is a substantial physiologic stressor for patients with SCD, even those who do not have high-risk characteristics at the time of surgery, and preoperative transfusion should be considered. A caveat is that extended phenotyping of transfused red cells should be performed, as discussed later in this chapter.

TABLE 43.6 **Transfusion Formulas**

Dilutional effects of transfusion on HbS: PRBC volume (PRBCV) (mL) = $(\text{Hct}_d - \text{Hct}_i) \times \text{TBV} \times \text{Hct}_{rp}\text{B}$

Manual partial-exchange transfusion:[a] $\text{HbSf} = 1 - (\text{PRBCV} \times \text{Hct}_{rp})$ $(\text{TBV} \times \text{Hct}_i) + (\text{PRBCV} \times \text{Hct}_{rp}) \times \text{HbS}_i\text{C}$

Automated exchange transfusion: Exchange volume (mL) = $(\text{Hct}_d - \text{Hct}_i) \times \text{TBVHct}_{rp} - (\text{Hct}_i + \text{Hct}_d)\text{2D}$

RBC volume (mL) = $\text{Hct}_i \times \text{TBV}$

[a] In these formulas, Hct and HbS are fractions (e.g., 40% = 0.4).
Hct_d, Desired hematocrit; Hct_i, initial hematocrit; Hct_{rp}, hematocrit of replacement cells (usually 0.75); HbS_i, initial HbS; HbS_f, final HbS; *PRBC*, packed red blood cells; *TBV*, estimated total blood volume in milliliters (children, 80 mL/kg; adults, 65 mL/kg; nomograms are available).
From Linderkamp et al., 1977, Springer-Verlag. From Nieburg and Stockman, 1977, American Medical Association.

Chronic partial-exchange transfusion is indicated in primary and secondary prevention of cerebral thrombosis as discussed in the Neurologic Complications section.

Transfusion complications include alloimmunization, delayed hemolytic transfusion reactions (DHTR; discussed in Exacerbations of Anemia), iron overload, and transmission of blood-borne diseases, including hepatitis C. The incidence of alloimmunization in SCD is between 19% and 30% and usually occurs with fewer than 15 transfusions.[147] Some patients seem to tolerate multiple transfusions without developing alloantibodies, but others are readily allosensitized. Alloimmunization to multiple RBC antigens often results in the development of autoantibodies which poses challenges in sourcing appropriately matched blood products.[148] The high rate of alloimmunization in transfused sickle cell patients is partly attributable to minor blood group incompatibilities between the recipient and donor pool, which often differ in ethnicity.[149,150] Ethnic mismatch of RBC antigens is not the only reason, however, as molecular analyses have revealed significant RH allelic diversity with mismatch between serological Rh phenotype and RHD or RHCE genotype in patients with SCD and African American blood donors.[151,152] Due to the prevalence of *RH* genetic diversity in patients with SCD, matching of the donor and recipient RBC antigens at the molecular level may be the only way forward to avoid alloimmunization and a recent study has demonstrated that this is feasible.[152] Antibodies against the C and E antigens of the Rh group, Kell (K) and Lewis, Duffy (Fya, Fyb), and Kidd (Jk) are common.[148] In the Stroke Prevention Trial in Sickle Cell Anemia, the routine use of WBC-reduced RBCs matched for E, C, and Kell decreased the allosensitization rate compared with historical data from 3% to 0.5% per unit transfused and decreased the rate of hemolytic transfusion reactions by 90%.[153] Therefore the recommended approach to preventing alloimmunization is to reduce leukocytes and perform extended phenotype matching for all patients (ABO, C, D, E, Kell, Kidd, Duffy, and S and s).[154] Many blood transfusion centers in the US have also adopted molecular genotyping using microarray chips for RBC phenotype prediction. The management of a DHTR and transfusional iron overload are discussed under Exacerbations of Anemia later in this chapter.

Transmission of human immunodeficiency virus, hepatitis B and C, and human T-cell leukemia/lymphoma virus-1 has diminished with improved screening of banked units but remains an issue. In addition to better screening programs, the use of leukocyte-depleted RBC transfusions can reduce this hazard.[154]

Phlebotomy

As mentioned, an Hb level of greater than 10 to 11 g/dL (hematocrit 30%) in the presence of substantial amounts of HbS (>30%) is associated with hyperviscosity. Symptoms of hyperviscosity are relatively non-specific and related to the affected vascular bed. Central nervous system hyperviscosity can be associated with central venous thrombosis or cerebral infarcts in patients with SCD. Some data indicate that phlebotomy to reduce the hematocrit and viscosity (and which may also address iron overload) can decrease the frequency of crises in HbSC or $\text{HbS}\beta^{+}$ disease.[155] In HbSS disease, phlebotomy has successfully been used in combination with HU (which increases the Hb level) in secondary stroke prevention in patients previously treated with chronic transfusion.[156] Phlebotomy alone has also been used in HbSS disease with baseline Hb levels of more than 9.5 g/dL with favorable results on the frequency and duration of pain crises. This benefit may have resulted from decreased hematocrit and viscosity and from a decrease in intracellular Hb concentration from iron deficiency.[157] One approach to phlebotomy is to remove approximately

10 mL/kg of blood over 20 to 30 minutes followed by infusion of an equal volume of normal saline. This is repeated every 2 weeks until the target Hb level of 9 to 9.5 g/dL is achieved.

Erythropoietin or Darbepoetin

The chronic hemolytic anemia of SCD is partially compensated by vigorous reticulocytosis. A decrease in compensatory reticulocytosis will exacerbate already existent anemia and can be expected to increase clinical risk. Accordingly, chronic relative reticulocytopenia (defined as Hb <9 g/dL and absolute reticulocyte count $<250{,}000 \times 10^9\,L^{-1}$) was identified as a significant risk factor for early mortality in a prospective cohort study of patients with SCD.[158]

In the general population, evaluation of EPO levels is usually prompted by the combination of anemia and abnormal serum creatinine level. EPO levels are then interpreted in relationship to the Hb level to assess for the possibility of EPO deficiency. In patients with SCD, this approach to diagnosis has pitfalls. Patients with SCD are already anemic; therefore, gradual anemia exacerbation is easily missed, and clinicians must weigh many possible causes in the context of multisystem SCD pathology. Furthermore, patients with SCD have low serum creatinine levels at baseline and serum creatinine is a poor measure of renal function due to tubular secretion even when renal function is abnormal. Therefore, a substantial increase in serum creatinine from baseline may nonetheless remain below the threshold defined as abnormal for the general population, potentially disguising the presence of renal damage that is sufficient to decrease renal endocrine function. Furthermore, EPO levels are not readily interpretable and generally inappropriately low in the individual patient with SCD as the EPO-producing cells in the renal medulla are unable to properly sense hypoxia due to tubular dysfunction.[159] One contributing factor could be increased uptake by the massive compensatory reticulocytosis. Further, EPO levels are lower in SCD adults than in children,[159] and EPO levels are inappropriately lower in patients with chronic relative reticulocytopenia.[59] Hence, EPO deficiency should be considered as a possible cause of progressive anemia in patients with absolute reticulocyte counts below $250{,}000 \times 10^9\,L^{-1}$ even if their serum creatinine levels are in the normal range. The cumulative published experience of EPO use in SCD is limited (52 patients).[160] Although EPO by itself has been reported to increase HbF levels, the most important role for EPO may be as replacement therapy for EPO deficiency that causes relative reticulocytopenia and progressive anemia. EPO replacement can also facilitate enhanced HU dosing and HbF augmentation.[160] In using recombinant human EPO, caution must be exercised not to elevate the hematocrit to levels that result in hyperviscosity. Also, the reticulocyte fraction is the most adhesive, and it is possible that EPO could exacerbate or trigger sickle cell crises.[160] Patients with SCD may be relatively resistant to EPO and require doses higher than those used in other patients with chronic renal failure. The reasons for EPO resistance are unclear but may include increased inflammation-mediated suppression of erythropoiesis which could explain favorable responses in some patients when initiation of EPO is accompanied by a dose of IV iron despite adequate iron stores as demonstrated by ferritin levels.[161]

EPO therapy is probably not indicated in patients receiving chronic transfusion therapy in whom encouraging endogenous HbS containing erythropoiesis may be counterproductive.

Iron Chelation

Early death is well described in association with iron overload in patients with β-thalassemia and hereditary hemochromatosis.[162,163] Similarly, iron overload is a problem in chronically transfused patients with SCD, although the clinical significance depends on the degree and duration of overload. Excess iron is a cause of significant morbidity and mortality in patients with SCD and one mechanism relates to hepatic fibrosis and hemosiderosis-related cirrhosis of the liver.[164] While individuals with SCD accumulate cardiac iron at a lower rate than thalassemia cohorts, they still remain at risk for cardiac hemosiderosis and cardiac iron deposition cannot be predicted by LIC. Cardiac iron monitoring utilizing non-invasive T2* MRI of the heart should be considered in patients who have undergone 5 to 8 years of transfusion therapy, or earlier in patients with markedly elevated ferritin or LIC.[165]

Chelation guidelines for patients with SCD are similar to those for other chronically transfused, iron-overloaded patients.[164,166] Steady state serum ferritin values should be no greater than 1000 to 1500 ng/mL (1000 to 1500 mcg/L). Notably, the serum ferritin level is not a good indicator of clinically significant iron overload.[167,168] When cardiac iron overload is present, an aggressive chelation regimen is warranted, given the potential risk for fatal cardiac arrythmias.

Iron chelation options in the United States include deferoxamine (via continuous intravenous or subcutaneous infusion), deferasirox (orally), and deferiprone. Optimal dosing of a chelating agent is determined by age, iron stores, frequency of transfusions, and the presence of organ dysfunction. There is some data to support greater effectiveness of the oral agents, in particular deferiprone, in cardiac iron unloading, and together with the oral route of administration and toxicity profile, deferasirox or deferiprone are favored over deferoxamine.[169–171] The side effect profile of deferasirox includes gastrointestinal symptoms; reversible, dose-dependent increases in serum creatinine; and liver dysfunction. Deferiprone carries a rare but significant risk of agranulocytosis in addition to hepatoxicity.

Newer FDA-approved methods of quantitating iron burden by FerriScan of the liver[172] can avoid the need for liver biopsies.

In addition to monitoring iron stores, formal audiograms should be performed prior to initiation of chelation therapy and annually thereafter. Hearing loss is most frequently reported with deferoxamine treatment, especially at higher doses. Annual evaluation by an ophthalmologist should be performed to screen for visual complications. Serum metabolic panel, urine protein, and creatinine should be monitored monthly in individuals on deferasirox, and every 3 months in those receiving deferoxamine. Liver function tests should also be closely monitored in patients on chelation therapy.

Anticoagulation or Antiplatelet Therapy

Although there is clear evidence of activation of the coagulation system in SCD, the role of thrombogenesis in VOCs remains unclear.[173] Similarly, there have been no thorough evaluations of the role of antiplatelet or antithrombotic agents for the treatment of SCD. D-dimer levels (a degradation product of cross-linked fibrin) increase during acute VOCs.[174]

Minidose heparin, 5000 to 7500 units every 12 hours, administered to four patients for 2 to 6 years reduced hospitalization and emergency department time by 75%, and pretreatment pain frequency recurred after heparin was discontinued.[175] Larger clinical studies will be required to better understand the risks and benefits of heparin therapy for acute VOCs in SCD. Heparin has not been studied for acute arterial stroke in patients with SCD but has a role in SCD-associated dural venous sinus thrombosis.[176] The management of stroke is fully discussed under Specific Complications and Their Management.

Acenocoumarol was administered in low doses that achieved a mean international normalized ratio (INR) of 1.64 and reduced the elevated levels of prothrombin activation fragment (fragment 1 +2) to 50% of pretreatment levels.[177] Clinical endpoints were not measured. In a crossover study, 29 patients were treated with acenocoumarol to target an INR of 1.6 to 2.0. No effect on crisis frequency was noted, although again, there were significant reductions in markers of coagulation system activation.[178] In 37 acutely ill sickle cell patients with elevated D-dimers, the effect of low-dose warfarin therapy (1 mg without a target INR) in 12 patients was examined. In multivariate analysis, low-dose warfarin was the only variable associated with a significant decrease in D-dimer levels, suggesting a warfarin-induced decrease in thrombin activity.[177] Therefore oral anticoagulation, even at low doses, is associated with a decrease in laboratory markers of coagulation pathway activation in SCD;

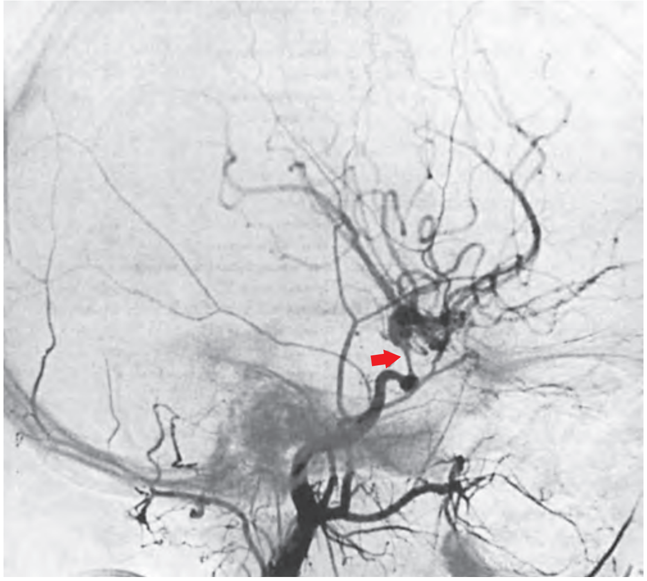

Figure 43.8 Right common carotid arteriogram taken in anteroposterior projection demonstrating complete occlusion of the origin of the right anterior cerebral artery *(arrowhead). (From Stockman JA, Nigro MA, Mishkin MM, Oski FA. Occlusion of large cerebral vessels in sickle-cell anemia. N Engl J Med. 1972;287:846.)*

however, further clinical trials are required to understand the clinical risks and benefits.

Platelet counts are often elevated and activated in patients with SCD.[179] Anti-platelet agents as potential anti-sickling agents, however, have been disappointing. Aspirin was the first anti-platelet drug to be considered; one study compared aspirin with placebo in 49 pediatric patients with SCD in a double-blind crossover study. The frequency and severity of crises were not affected by aspirin therapy, and aspirin did not significantly affect Hb levels.[180] Cerebral thrombosis, which accounts for 70% to 80% of all CVAs in SCD, results from large-vessel occlusion (Fig. 43.8) rather than the more typical microvascular occlusion of SCD. In the United States, a clinical trial testing the safety and efficacy of aspirin in diminishing the incidence and progression of cognitive defects and overt or silent stroke in pediatric patients (START) was completed in 2009 but to date, the results of this study have not appeared in print. Antiplatelet therapy with clopidogrel in patients with SCD, unfortunately, was also disappointing. New, third-generation P2Y12 inhibitors such as ticagrelor and prasugrel have also been studied in patients with SCD. Although prasugrel showed appropriate levels of anti-platelet aggregation compared to healthy patients in ex vivo studies, and was well tolerated by patients, in a phase III (DOVE) study involving 341 children and adolescents, there was no significant difference in the rate of VOCs between the treatment group and placebo, and the study was terminated early.[181,182] Ticagrelor, in a phase IIB study, was well tolerated, but failed to show effect in the frequency of VOC.[183] While aspirin as an anticoagulant therapy did not provide benefit over placebo, it continues to be used as an analgesic in many parts of Africa.[184]

The management of stroke risk and stroke is fully discussed under Specific Complications and Their Management.

Experimental Therapies

Gene-based studies using different therapeutic strategies are currently ongoing, some in their early stages.[185,186] Studies directed at the *BCL11A* gene for therapeutic reactivation of fetal hemoglobin show great promise and include two different experimental approaches: (1) addition of a lentiviral vector encoding a short hairpin RNA (shRNA) targeting erythroid-specific expression of BCL11A, thus encouraging endogenous HbF production[187]; (2) using CRISPR/Cas9-mediated gene editing to disrupt the erythroid-specific enhancer of the *BCL11A* gene.[188] Precise correction of the sickle mutation converting the sickle allele to a normal β-globin allele is the most direct approach but the approach is still fraught with challenges.

Specific Complications and Their Management

Pain Crisis

Acute Pain Episode or Crisis

Acute pain is the first symptom of disease in more than 25% of patients and is the most frequent symptom after age 2 years.[189] Pain is the complication for which patients with SCD most commonly seek medical attention.[190] An episode of acute pain was originally called a “sickle cell crisis” by Diggs, who used the expression “crisis” to refer to any new rapidly developing syndrome in the life of a patient with SCD.[191] Pain crises result from vaso-occlusion of the bone marrow vasculature causing bone infarction, which in turn releases inflammatory mediators that activate afferent nociceptors.[192]

Although a general correlation of vaso-occlusive severity and genotype has been posited,[193] there is tremendous variability within genotypes and in the same patient over time. In one large study of patients with HbSS disease, one-third rarely had pain, one-third were hospitalized for pain approximately two to six times per year, and one-third had more than six pain-related hospitalizations per year.[194] Over a 5-year period in the National Cooperative Study of SCD, 40% of patients had no painful episodes, and 5% of patients accounted for one-third of the emergency department visits. Pain is more frequent with the HbSS genotype, low levels of HbF, higher Hb levels,[57] and sleep apnea.[195] The frequency of pain peaks between ages 19 and 39 years. After the age of 19 years, more frequent pain correlates with a higher mortality rate.[57] Medical personnel who see patients only in the emergency department gain a biased view of SCD skewed by a frequently affected minority with severe disease.[196,197]

Pain may be precipitated by events such as cold weather and extreme heat which may induce rapid cooling of the skin via sweating,[198] dehydration, infection, stress, menses, and alcohol consumption. Underlying etiologies should be searched for and corrected, but the majority of painful episodes have no identifiable cause. Pain can affect any area of the body, most commonly the back, chest, extremities, and abdomen; may vary from trivial to excruciating; and is usually endured at home without a visit to the emergency department. There may be premonitory symptoms.[199] In adults, the average length of hospital admission is 7.5 days in contrast to only 4.4 days in children.[199] Painful episodes are biopsychosocial events caused by vaso-occlusion in an area of the body having nociceptors and nerves.[200] Pain is an effect and, as such, consists of sensory, perceptual, cognitive, and emotional components. Frequent pain generates feelings of despair, depression, and apathy that interfere with everyday life and promote an existence that revolves around pain. This scenario may lead to a chronic debilitating pain syndrome in some patients.

There is no specific clinical or laboratory finding pathognomonic of pain crisis. The diagnosis is established by history and physical examination. Changes in steady-state Hb values, hemolytic parameters, sickled cells on blood smear, and WBC counts are not reliable indicators. Numerous laboratory tests, leukocytosis, D-dimer, fragments of fibrin, and markers of platelet activation have been found to lack specificity as indicators of acute vaso-occlusion. Often patients can tell if they are having a typical pain crisis or something more sinister. It is thus good practice to ask the patient if symptoms are representative of their usual pain crisis.

Initial medical assessment should focus on detection of triggers or medical complications requiring specific therapy, which include viral or bacterial infection, dehydration, ACS (fever, tachypnea, chest pain, hypoxia, and chest signs), severe anemia, cholecystitis, splenic enlargement, neurologic events, and priapism.[200,201] Pain management should be aggressive to make the pain tolerable and enable patients to attain maximum functional ability. To make the patient pain free is an unrealistic goal and risks oversedation and hypoventilation, which must be avoided. A pain chart should be started and analgesia titrated against the patient's reported pain together with medical assessment of the patient's overall clinical status.[201,202] When clinicians consistently observe a disparity between patients' verbal self-report of their pain and their ability to function, further assessment should be performed to ascertain the reason for disparity. Patients are often undertreated for pain because many physicians and healthcare providers are overly concerned with the potential for addiction. Undertreatment of pain is no more desirable than overtreatment and oversedation; undertreatment can prolong the duration of a painful episode and can weaken the relationship between a patient and their healthcare providers. The benefit of early and aggressive treatment of pain was demonstrated in a study that incorporated rapid administration of intravenous morphine with the addition of long acting opioid therapies in 50 patients with SCD; overall, emergency department visits decreased and hospital admissions and length of stay dramatically declined in patients with the greatest frequency of acute pain episodes.[203] Many centers have incorporated protocols and guidelines for rapid treatment of acute pain in day hospital settings which results in a striking reduction in emergency room visits and admission rates, as well as healthcare associated costs.

The pain pathway should be targeted at different points with different agents, avoiding toxicity with any one class (Table 43.7). The mainstays are nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and opioids. NSAIDs can be used to control mild to moderate pain and may have an additive role in combination with opioids for severe pain. The most potent NSAID is ketorolac. NSAIDs should be used with caution in those with a history of peptic ulcer disease, renal insufficiency, asthma, or bleeding tendencies. Within limits, use the agents that the patients know work for them and avoid meperidine (Demerol), which should only be used under very exceptional circumstances. Sedatives and anxiolytics alone should not be used to manage pain because they can mask the behavioral response to pain without providing analgesia.

Treatment of persistent or moderate to severe pain should be based on increasing the opioid strength or dose.[201] In assessing patient responses to conventional doses of analgesia, it must be remembered that individuals with SCD metabolize narcotics rapidly.[201] One approach is to administer morphine 0.1mg/kg SLT intravenously or subcutaneously every 20 minutes until pain is controlled. The patient should be checked at 20-minute intervals for pain; respiratory rate, depth, and quality; and sedation until the patient is stable with adequate pain control. Subsequently, the patient should receive a maintenance dose of 0.05 to 0.15 mg/kg SLT intravenously or subcutaneously every 2 to 4 hours. A rescue dose of 50% of the maintenance dose can be considered on an as-needed basis every 30 minutes for breakthrough pain.

During maintenance with opioids, pain control, respiratory rate, depth, and quality, and oxygen saturation should be monitored approximately every 2 hours. If respiratory depression is noted, omit the maintenance dose of morphine. For severe respiratory depression or oxygen desaturation, administer naloxone. Incentive spirometry and mandatory time out of bed are helpful in patients with chest pain to decrease the risk for hypoventilation. Severe or intractable pruritus is a common problem encountered in patients requiring high doses of opioids necessitating non-sedating antihistamine therapy or the

TABLE 43.7 Recommended Dose and Interval of Analgesics Necessary to Obtain Adequate Pain Control in Patients With Sickle Cell Disease

	Dose/Rate	Comments
Severe to Moderate Pain		
Morphine	Parenteral: 0.1–0.15 mg/kg every 3–4 h Recommended maximum single dose, 10 mg PO: 0.3–0.6 mg/kg every 4 h	Drug of choice for pain; lower doses in elderly adults and infants and in patients with liver failure or impaired ventilation
Meperidine	Parenteral: 0.75–1.5 mg/kg every 2–4 h Recommended maximum dose, 100 mg PO: 1.5 mg/kg every 4 h	Increased incidence of seizures; avoid in patients with renal or neurologic disease and those who receive MAOIs
Hydromorphone	Parenteral: 0.01–0.02 mg/kg every 3–4 h PO: 0.04–0.06 mg/kg every 4 h	
Oxycodone	PO: 0.15 mg/kg/dose every 4 h	
Ketorolac	IM: Adults: 30 or 60 mg initial dose followed by 15–30 mg; children: 1 mg/kg load followed by 0.5 mg/kg every 6 h	Equal efficacy to 6 mg MS; helps narcotic-sparing effect; not to exceed 5 days; maximum, 150 mg first day, 120 mg maximum on subsequent days; may cause gastric irritation
Butorphanol	Parenteral: Adults: 2 mg every 3–4 h	Agonist–antagonist; can precipitate withdrawal if given to patients who are being treated with agonists
Mild Pain		
Codeine	PO: 0.5–1 mg/kg every 4 h Maximum dose, 60 mg	Mild to moderate pain not relieved by aspirin or acetaminophen; can cause nausea and vomiting
Aspirin	PO: Adults: 0.3–6 mg every 4–6 h; children: 10 mg/kg every 4 h	Often given with a narcotic to enhance analgesia; can cause gastric irritation; avoid in febrile children
Acetaminophen	PO: Adults: 0.3–0.6 g every 4 h; children: 10 mg/kg	Often given with a narcotic to enhance analgesia
Ibuprofen	PO: Adults: 300–400 mg every 4 h; children: 5–10 mg/kg every 6–8 h	Can cause gastric irritation
Naproxen	PO: Adults: 500 mg/dose initially and then 250 every 8–12 h; children: 10 mg/kg/day (5 mg/kg every 12 h)	Long duration of action; can cause gastric irritation
Indomethacin	PO: Adults: 25 mg every 8 h; children: 1–3 mg/kg/day given 3 or 4 times	Contraindicated in psychiatric, neurologic, renal diseases; high incidence of gastric irritation; useful in gout

IM, Intramuscular; *MAOI*, monoamine oxidase inhibitor; *MS*, morphine sulphate; *PO*, oral.
Adapted from Charache S, Terrin ML, Moore RD, et al. Effect of hydroxyurea on the frequency of painful crises in sickle cell anemia. Investigators of the Multicenter Study of Hydroxyurea in Sickle Cell Anemia. *N Engl J Med*. 1995;332:1317.

addition of a 5-HT3 receptor antagonist. Laxatives or stool softeners should be prescribed to prevent opioid-induced constipation.

When intravenous dosing of opioids is roughly equivalent to home doses of oral medications, consider gradually tapering the dose by 10% to 20% at a time and subsequently switching from parenteral to oral administration of opioids once pain symptoms have stabilized. In general, opioids should be tapered by decreasing the dose rather than by increasing the interval between doses. For adult patients whose pain requires several or many days to resolve, a sustained-release opioid preparation is appropriate and provides more consistent analgesia.

Hydration is a critical part of management. However, cardiac function may be significantly impaired, especially in adult patients, and caution should be exercised with intravenous fluid management to avoid iatrogenic fluid overload. Patients with SCD cannot concentrate their urine and are at risk for dehydration when not taking adequate fluids (60 mL/kg/24 h in adults). Intravenous hydration is indicated when the patient is not taking oral fluids adequately. Ideally, the urine specific gravity should be kept under 1.010 daily. Hb may decrease by 1 to 2 g/dL in an uncomplicated pain crisis; blood transfusion is not routinely indicated for an uncomplicated pain crisis.

Equianalgesic doses of oral opioids should be prescribed for home use when necessary to maintain the relief achieved in the emergency department or hospital. Care should be taken to appropriately taper opioids in patients who have received daily opioids over many days. In these patients, there may be physical opiate dependence, which is characterized by the onset of acute withdrawal symptoms upon cessation of opioid administration. For patients at risk for physical dependence, opiates should be titrated downward by 15% to 20% per day. All patients with SCD should receive pain prescriptions from the hospital pharmacy prior to discharge; discharge without opioid medications is associated with higher 30-day readmission rates.[204] A follow-up visit in the outpatient clinic should be scheduled within one to two weeks of discharge.

If the patient is not taking a disease-modifying agent such as HU, consideration should be given to initiating such therapy either as an inpatient or during follow up in the outpatient setting (see Case 1).

Chronic Pain

Chronic pain occurs in at least 29% of adults with SCD and is most frequently reported in those 25 to 44 years of age.[205] The mechanisms of chronic pain in SCD remain poorly understood and are multifactorial secondary to a number of biopsychosocial variables. In the post-hematopoietic stem cell transplantation setting, a subgroup of patients with SCD have persistence of chronic pain despite reversal of the underlying disease process, suggesting that individual and environmental factors play a role in pain phenotype.[206] Chronic pain can be challenging to treat and involvement of Palliative Care specialists early in the disease course is highly recommended.

Adequate analgesia with both short- and long-acting opiates is important to maintain the psychosocial functioning of patients who suffer from chronic pain. Underlying identifiable etiologies including avascular necrosis, early degenerative changes, or osteoarthritis should be addressed with orthopedic evaluation and potentially joint replacement in the case of femoral head necrosis. Agents including gabapentin, amitriptyline, and some antiseizure medications[207] can address neuropathic components and decrease the sleep impairment that can occur with chronic pain. Given the high incidence of comorbid depression, all individuals should be screened for depressive symptoms and be considered for pharmacotherapy if major depressive disorder is diagnosed. Several antidepressants, including serotonin and norepinephrine reuptake inhibitors (SNRIs), are effective in the treatment of chronic pain and can be considered after consulting with mental health professionals and considering side effect profiles.

Chronic Anemia

Chronic hemolytic anemia is one of the hallmarks of SCD. Sickle erythrocytes are destroyed randomly, with a mean life span of about 17 days.[208] The overall hemolytic rate reflects the number of ISCs.[209] The degree of anemia is most severe in SCA (HbSS), and HbSβ°-thalassemia, milder in HbSβ$^+$-thalassemia and HbSC disease,[210] and, among patients with SCA, less severe in those who have coexistent α-thalassemia (Table 43.8 and see Table 43.1).[211]

CASE 1

A 40-year-old African American female with sickle cell anemia complicated by frequent VOC, and sickle cell nephropathy, presented with acute pain and was subsequently hospitalized for IV analgesia and supportive care. Admission hemoglobin was 7.9 g/dL with elevated hemolytic parameters from baseline consistent with acute pain crisis. She was initiated on IV hydromorphone, parenteral NSAIDs for the first 24 hours, and subsequently transitioned to a hydromorphone PCA on Day 2 of hospitalization for improved pain control. She stabilized with conservative management but on Day 5 of hospitalization developed chest pain associated with mild dyspnea, non-productive cough, and low-grade fever.

Physical evaluation was notable for a new onset hypoxia (SpO$_2$ 88% on room air), tachypnea, fever, and the patient was also mildly distressed. Apart from decreased breath sounds in the right lower lung base, the rest of the physical exam was unremarkable. The patient's hypoxia resolved on 2 L nasal cannula and the patient was encouraged to use incentive spirometry. Chest radiography (CXR) and contrast-enhanced chest computed tomography (CT) demonstrated basilar airspace opacities involving the right lower and middle lobes. Repeat CBC showed that the Hb had dropped to 7.3 g/dL.

Question 1: What is your provisional diagnosis and what are your next steps in management?

Answer 1: Acute chest syndrome complicating acute pain crisis; obtain stat blood cultures and initiate broad-spectrum empiric antibiotic therapy. A simple top-up blood transfusion of 1–2 units pRBC to Hb below 10 g/dL is recommended.

The patient defervesced and stabilized after initiation of antibiotic therapy, however, after 24 h, fever recurred with worsening hypoxia. Arterial blood gas demonstrated hypoxemia with an arterial oxygen partial pressure to fractional inspired oxygen ratio of 89 mm Hg. In the setting of worsening tachypnea with concern for impending respiratory failure, the patient was transferred to the ICU, endotracheal intubation was performed, and the patient was placed on mechanical ventilation. Total Hb was 7.9 g/dL with 48.6% HbS.

Question 2: What is your next step in management?

Urgent exchange transfusion to reduce HbS fraction, continue intravenous hydration at maintenance rate and broad-spectrum empiric IV antibiotics.

Blood culture data remained negative. Her condition remarkably improved after 36 hours. She had an uneventful extubation and was safely discharged home after a total 13-day hospital stay.

ACS is often preceded by febrile episodes in children and by vaso-occlusive pain crisis in adults. Rapid recognition of ACS and prompt clinical intervention are necessary to prevent adverse health outcomes, especially in adults. Mainstays of treatment include judicious use of opioid analgesics to prevent respiratory compromise, supplemental oxygen therapy and arterial blood gas assessment, frequent use of bedside incentive spirometry in conjunction with respiratory therapy and empiric antibiotics, typically a cephalosporin and macrolide. Simple or exchange transfusion are indicated for the acute treatment of ACS; the decision to pursue exchange transfusion depends on the clinical severity and progression of ACS as well as the level of hemoglobin. If the patient is not on hydroxyurea (HU), initiate HU therapy at outpatient follow-up and encourage adherence to HU if the patient is on therapy to reduce/prevent future ACS episodes.

As already noted, EPO deficiency from otherwise subclinical chronic renal damage may also contribute to a decline in Hb levels below baseline. The level of chronic anemia is a significant prognostic marker in SCD.[59]

The treatment options for the chronic anemia of SCD have already been discussed earlier in this chapter.

TABLE 43.8 **Bacteria and Viruses That Most Frequently Cause Serious Infection in Patients With Sickle Cell Disease**

Microorganism	Type of Infection	Comments
Streptococcus pneumoniae	Septicemia	Common despite prophylactic penicillin and pneumococcal vaccine
	Meningitis	Less frequent than in years past
	Pneumonia	Rarely documented except in infants and young children
	Septic arthritis	Uncommon
Haemophilus influenzae type b	Septicemia	
Meningitis		
Pneumonia	Much less common in recent years because of immunization with conjugate vaccine	
Salmonella species	Osteomyelitis	
Septicemia	Most common cause of bone and joint infection	
Escherichia coli and other gram-negative enteric pathogens	Septicemia	
Urinary tract infection		
Osteomyelitis	Focus sometimes not apparent	
Staphylococcus aureus	Osteomyelitis	Uncommon
Mycoplasma pneumoniae	Pneumonia	Pleural effusions; multilobe involvement
Chlamydia pneumoniae	Pneumonia	
Parvovirus B19	Bone marrow suppression (aplastic crisis)	High fever common; rash and other organ involvement infrequent
Hepatitis viruses (A, B, and C)	Hepatitis	Marked hyperbilirubinemia

Data from Buchanan GR, Glader BE: Benign course of extreme hyperbilirubinemia in sickle cell anemia: Analysis of six cases. *J Pediatr.* 1977;91:21.

Exacerbations of Anemia

The constant level of hemolytic anemia may be exacerbated by additional events including aplastic crises, acute splenic or hepatic sequestration, chronic renal disease, acute kidney failure on a background of chronic renal disease, renal endocrine deficiency that may be present without overt renal failure, bone marrow necrosis, deficiency of folic acid or iron, DHTR, autoimmune hemolytic anemia, or hyperhemolysis. Laboratory evaluations that are very useful in the evaluation of a patient with an abrupt decline in baseline Hb level are the reticulocyte count, liver aspartate transaminase (AST), LDH, alloantibody screening, direct antiglobulin (Coombs) test, and EPO levels.

Aplastic Crises

Aplastic crises are transient arrests of erythropoiesis characterized by abrupt falls in Hb levels, reticulocyte number (typically, reticulocytes <1.0%, absolute reticulocyte count <10,000 per μL), and RBC precursors in the bone marrow without necessarily an increase in the LDH. Although these episodes typically last only a few days, severe anemia may develop in the setting of continued hemolysis in the absence of RBC production. Significant cardiac decompensation can occur if anemia and reticulocytopenia are not promptly recognized and treated. Although the mechanisms that impair erythropoiesis in inflammation are operative in infections of all types (see Chapter 36), human parvovirus B19 specifically invades proliferating erythroid progenitors resulting in cytotoxicity, which accounts for its importance in SCD (see Chapters 33 and 35).[212] Reticulocytopenia secondary to parvovirus B19 infection lasts approximately 7 to 10 days. Parvovirus B19 (Fig. 43.9) accounts for 68% of aplastic crises in children with SCD,[213] but the high incidence of protective antibodies in adults makes parvovirus a less frequent cause of aplasia in this age group (see also Infections, later in this chapter). Other reported causes of transient aplasia are infections by *S. pneumoniae*, *Salmonella*, streptococci, and Epstein-Barr virus. Bone marrow necrosis, which also may be the result of parvovirus infection, characterized by fever, bone pain, reticulocytopenia, and a leukoerythroblastic response, also causes aplastic crisis.[214,215]

Inhaled oxygen therapy also causes transient RBC hypoproduction; supraphysiologic oxygen tensions curtail EPO production promptly and suppress reticulocytosis within 2 days.[216]

The mainstay of treating aplastic crises is RBC transfusion. When transfusion is necessitated by the degree of anemia or cardiopulmonary symptoms, a single PRBC transfusion may suffice because reticulocytosis may resume spontaneously within a few days. Transfusion may be avoided by keeping severely anemic patients on bed rest to prevent symptoms and by avoiding supraphysiologic oxygen tensions. A useful guideline for transfusion in the context of an aplastic crisis is the reticulocyte count. A patient having an aplastic crisis with a reticulocyte count that is recovering is less likely to require urgent transfusion than one with a normal or low absolute reticulocyte count.

Sequestration Crisis (Spleen or Liver)

Acute splenic sequestration of blood is characterized by acute exacerbation of anemia, persistent reticulocytosis, a tender, enlarging spleen, and is sometimes accompanied by hypovolemia.[217] The LDH level may remain stable or increase and thrombocytopenia may also be present. Patients susceptible to this complication are those whose spleens have not undergone fibrosis including young patients with HbSS disease and adults with HbSC disease or sickle cell–β^+-thalassemia. Sequestration may occur as early as a few weeks of age and may cause death before SCD is diagnosed. In one study, 30% of children had splenic sequestration over a 10-year period and 15% of the attacks were fatal.[218]

The basis of therapy is to restore blood volume and RBC mass, thereby preventing evolution to hypovolemic shock. Because splenic sequestration recurs in 50% of cases, follow up management is imperative. For children older than age 2 to 3 years, splenectomy is recommended shortly after the acute event has abated. Alternatively, chronic transfusion therapy is used in young children to delay splenectomy until it can be tolerated safely but such practices have only been partly successful in the prevention of recurrence. Age of the first episode is predictive of recurrence—risk is lower when the first episode occurs after 2 years compared to before 1 year of age.[219] Because recurrence is possible during transfusion therapy, parents should be trained to detect a rapidly enlarging spleen and to seek immediate medical attention in this event. Elective splenectomy should be considered in older patients with chronic hypersplenism. Less common sites of acute sequestration include the liver and possibly the lung.[220,221]

Delayed Hemolytic Transfusion Reaction and Autoimmune Hemolytic Anemia

DHTR are potentially life-threatening complications. They are under-recognized in patients with SCD in particular because the symptoms mimic those of acute VOCs, and serological markers of new alloantibodies may be equivocal.[222,223] HTRs occur primarily

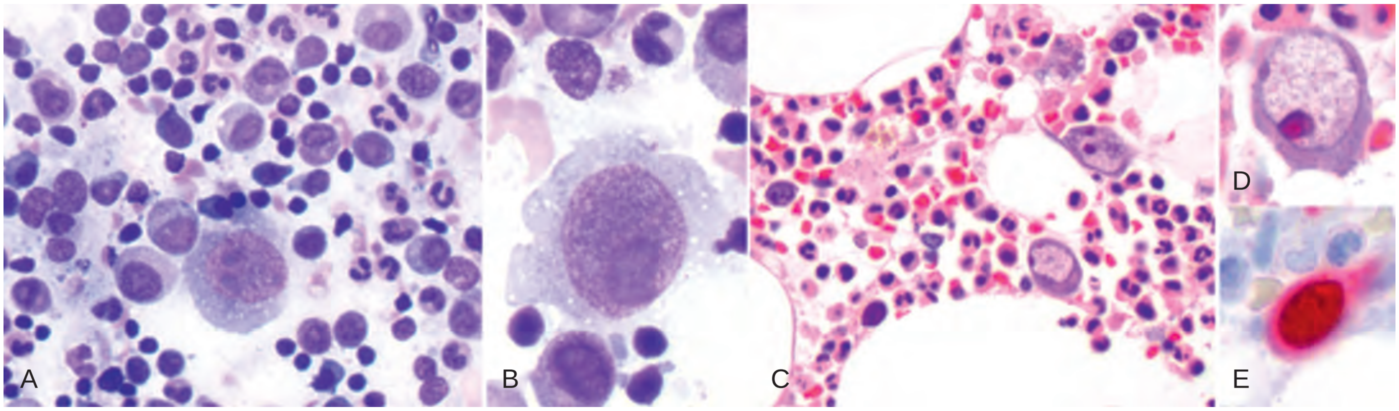

Figure 43.9 PARVOVIRUS. Bone marrow aspirate in a patient with sickle cell disease and aplastic crisis (A). Note the absence of red blood cell precursors except for the single, large degenerating pronormoblast *(lower center)*. Such pronormoblasts contain large nuclear inclusions (B) as a result of replication of parvovirus B19. The same can be seen in the tissue sections of a bone core biopsy (C and D). The parvovirus can now be recognized immunohistochemically with an immunostain (E).

in RBC alloimmunized patients, and approximately 30% of patients with SCD are predisposed to develop alloantibodies, in part because of minor blood group incompatibilities in racially mismatched blood.[149,150] Mismatch of RBC antigens, however, does not fully explain observed rates of alloimmunization given that a significant percentage of patients who receive phenotypically matched blood exclusively from ethnically matched donors still become alloimmunized.[152,224] Molecular analyses have demonstrated significant RH allelic diversity with mismatch between serological Rh phenotype and RHD or RHCE genotype in patients with SCD and African American blood donors.[150,152]

After alloimmunization, there is a subsequent decrease in antibody titer that can fall below serologically detectable levels. Therefore antigen-positive RBCs appear compatible in cross-matching and are transfused. This can result in a DHTR produced by the amnestic response of the immune system as opposed to the immediate hemolytic reaction that occurs with preformed antibody. The DHTR consists of an unexplained acute fall in Hb, elevated LDH level, elevated bilirubin levels above baseline, and hemoglobinuria, typically occurring between 4 and 10 days after the RBC transfusion.[223,224] Delayed hemolytic reactions and hyperhemolysis have been shown to occur in 11% of pediatric patients with SCD and a history of alloantibodies.[225] In a recent prospective analysis of an adult SCD cohort, DHTRs occurred following 4.2% of episodic transfusions and were associated with significant mortality—approximately 11% of patients who experienced DHTR died.[226]

In SCD, the DHTR can be particularly devastating because it can be accompanied by reticulocytopenia, which together with a bystander effect of destruction of recipient blood (not just donor blood) can result in unanticipated worsening of anemia to levels below that seen before transfusion.[223,227] In addition to the manifestations of a DHTR as listed, patients may develop acute congestive heart failure, acute renal failure, or ACS accompanied by vaso-occlusive pain crisis. Subsequent transfusions may further exacerbate ongoing hemolysis and worsen anemia.

Resolution of severe anemia may only occur after withholding further transfusions with subsequent reticulocyte count recovery. Corticosteroids at high doses (e.g., intravenous methylprednisolone 500mg/day for 2 to 3 days) should be considered if the anemia is life threatening or if further transfusion is deemed necessary to save the patient's life. Intravenous immunoglobulin can also be considered, with proper attention paid to avoiding iatrogenic fluid overload. Intravenous iron and EPO are often administered concurrently to accelerate endogenous RBC production in the setting of severe anemia.[228] Cases of severe DHTR and hyperhemolysis are driven by extensive complement activation. Treatment with the anti-C5 complement-blocking antibody, eculizumab, has been shown to reduce hemolysis and result in rapid clinical improvement.[229,230] If emergency transfusion of least compatible blood is deemed necessary in the setting of severe anemia or multi-organ failure, rituximab prophylaxis has demonstrated efficacy in several case reports.

Approaches to minimizing this complication include transfusing extended-matched (see Basic Management and Disease Modification), phenotypically compatible blood.[148,150,153,223,228] Extended RBC antigen molecular typing in recipients of chronic or episodic transfusions has been implemented in many centers across the US. Blood banks maintain records of previously identified alloantibodies to reduce the risk of re-exposure to a particular alloantigen once an alloantibody has been detected. Effective communication with other healthcare systems which have previously transfused the patient is paramount. Complex alloantibody profiles obtained from other institutions should be honored when sourcing compatible blood products even when in-house serological testing does not detect alloantibodies. Unfortunately, limited or inadequate alloimmunization histories may result from multiple patient encounters in various healthcare systems; there is a great need for a universal platform in which laboratory information exchange between institutions can occur rapidly.

Recognition of DHTR is vital; not only is DHTR itself potentially life-threatening, but giving a further transfusion in this setting can prove fatal. Diagnosis of DHTR is best made by simply being aware of DHTR when patients present with acute pain following a recent transfusion. This syndrome may or may not recur with further transfusions after a recovery period (see Case 2).[231]

Hyperhemolytic Crisis

Hyperhemolytic crisis is the sudden exacerbation of anemia with increased reticulocytosis and bilirubin level. If suspected, the approach to management should first be to look for an underlying etiology, which may be one of the events listed earlier: aplastic crisis (during the recovery phase when the reticulocyte count may not be decreased), sequestration crisis, DHTR, or autoimmune hemolysis. Another possible cause is glucose-6-phosphate dehydrogenase deficiency.[232]

Hypothyroidism

Iron overload in SCD can result in hypothyroidism.[233] Therefore hypothyroidism is another etiology to consider in a patient with SCD with an otherwise unexplained decrease in Hb below baseline.

Infections

Immune Deficit

The propensity of children with SCD to contract *S. pneumoniae* infection is related to impaired splenic function[234] and diminished serum opsonizing activity. Even before the anatomic autoinfarction of the spleen in patients with SCA, defective splenic function is demonstrable by Howell-Jolly bodies on the peripheral blood smear, visible

CASE 2: DELAYED HEMOLYTIC TRANSFUSION REACTION AND HYPERHEMOLYSIS

A 30-year-old female with HbSS disease on hydroxyurea therapy, congenital atrophic right kidney, and proteinuria was evaluated for acute pain and the onset of dark, "Coca-Cola"-colored urine. On further questioning, the patient endorsed a recent hospitalization at an outside hospital for VOC accompanied by ACS and reportedly received 2 units of packed RBCs, 8 days prior to current presentation. She had no known history of alloimmunization. At this visit, her Hb had decreased below her baseline to 7.7 g/dL accompanied by marked elevations in LDH (1500) and total and indirect bilirubin levels and acute kidney injury (AKI) with a serum creatinine of 1.49 mg/dL. Urinalysis demonstrated positive bilirubin, 3 plus hemoglobin, and 34 RBCs.

Question 1: What is your provisional diagnosis and what tests would you perform at this point?

Acute sickle pain triggered by a delayed hemolytic transfusion reaction (DHTR) and initiate full evaluation of DHTR.

Further investigations showed a positive direct antiglobulin (Coombs) test (DAT) for IgG and negative for complement, but all clinically significant alloantibodies were ruled out.

By the following morning, her Hb had declined further to 5.5 g/dL in the setting of persistent AKI; the patient remained hemodynamically stable and relatively asymptomatic.

Question 2: What is the next step in management?

Initiate IV steroids and IVIG in addition to a single dose of IV iron and ESA therapy to support endogenous RBC production.

Despite appropriate management for DHTR, the patient's anemia continued to worsen with marked elevations in LDH and persistent hemoglobinuria. On the fourth day of hospitalization, the Hb level decreased to 3.6 g/dL.

Question 3: What is the next step in management?

It is clear from the drop in hemoglobin to below baseline that the patient's own red cells are also being destroyed, a situation referred to as "hyperhemolysis." The patient requires a life-saving blood transfusion to prevent end-organ damage, specifically, worsening renal injury. Given concern for DHTR-associated hyperhemolysis and lack of response to steroids and IVIG, eculizumab, a C5 complement inhibitor which impedes complement activation, was administered. She subsequently received 2 units of pRBCs. Given the known risk for invasive meningococcal disease in patients treated with eculizumab, the meningococcal vaccine was administered to the patient. The majority of patients with SCD receive meningococcal vaccination in childhood. The patient's Hb levels gradually stabilized over the ensuing days without additional blood transfusion; she achieved a Hb level to 6.5 g/dL prior to discharge. Hydroxyurea therapy was resumed with resolution of AKI.

Delayed hemolytic transfusion reactions are under-recognized in patients with SCD because symptoms mimic those of acute vaso-occlusive crises and serological markers of new alloantibodies may be equivocal. Recognition of DHTR is vital; not only is DHTR itself potentially life-threatening, but administering further transfusions in this setting can prove fatal. It is important to continue screening for allo-antibodies.

"pits" on the surface of RBCs, and abnormal results of radionuclide spleen scanning.[235] Specific syndromes exhibiting greater rates of hemolysis cause loss of splenic function at earlier ages—HbSS disease earlier than HbSC disease earlier than HbSβ^+-thalassemia.

Infectious complications of SCD are a major cause of morbidity and mortality[236] even with current vaccination and prophylactic antibiotic regimens. The infections caused by particular organisms are shown in Table 43.8, and the specific organisms affecting different target organs are shown in Table 43.9. By 5 years of age, almost all patients are functionally asplenic, contributing to infectious susceptibility. Historically, pneumococcal sepsis has been the predominant cause of death in those younger than 20 years of age.[237]

Evaluation

The most critical aspect of infectious illness in SCD is the evaluation and treatment of febrile episodes. Routine evaluation includes a history for localizing symptoms, physical examination with assessment of vital signs for hemodynamic instability and/or hypoxia, CBC with differential and reticulocyte count, urinalysis, peripheral blood and urine cultures, a lumbar puncture if meningitis is suspected, and chest radiography or computed tomography (CT) to evaluate for pneumonia. Results of the CBC are compared with baseline values. A left shift in the differential count suggests bacterial infection. Patients presenting with acute fever should promptly receive empiric parenteral antibiotics, ideally within 60 minutes from triage.

Streptococcus pneumoniae, Haemophilus influenzae, Atypical Mycobacteria, and Acute Febrile Illness

S. pneumoniae bacteremia is accompanied by leukocytosis, a left shift, aplastic crisis, sometimes disseminated intravascular coagulation, and a 20% to 50% mortality rate.[237] Although concerns about *S. pneumoniae* sepsis are largely for young children, this complication also occurs in adults, often with devastating results.[238] *S. pneumoniae* is the major cause of meningitis in infants and young children with SCD, and it occurs in the setting of bacteremia.

The second most common organism responsible for bacteremia in these children, *H. influenzae* type b, accounts for 10% to 25% of episodes. *H. influenzae* bacteremia affects older children and is less fulminant than *S. pneumoniae* bacteremia, but it may be fatal.[237] Conjugated *H. influenzae* type b vaccines produce excellent antibody responses in children with SCD and are now administered in early infancy (http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm).

Owing to the high mortality rate of bacteremia, hospitalization and parenteral antibiotics have been the standard of care for children with fevers higher than 38.5°C. Prompt attention to fever can reduce the risk of severe pneumococcal sepsis. Rapid administration of antibiotics has resulted in a lower incidence of meningitis among patients with bacteremia than 20 years ago when the incidence was 50%.[239] The efficacy of ceftriaxone therapy for *S. pneumoniae* and *H. influenzae* infection[240] has led to new treatment algorithms that recommend outpatient therapy for most patients. However, resistant *S. pneumoniae* have emerged, necessitating a thorough knowledge of local resistance patterns to guide the choice of alternate antibiotics (particularly vancomycin, to which resistance has not been observed).

See the section on Pulmonary Complications for further discussions regarding pneumonia and ACS.

Meningitis

Meningitis therapy should cover *S. pneumoniae* and probably *H. influenzae* type b and should be continued for at least 2 weeks.

Salmonella and Osteomyelitis

In this patient population, osteomyelitis is commonly caused by *Salmonella* spp.[241] *Staphylococcus aureus*, the most common etiology in patients without SCD, accounts for less than 25% of SCD cases. These complications are more frequent in children due to the vasculature of immature bone that is conducive to hematogenous spread, but adults can also be affected. Infection usually affects long bones, often at multiple sites. Clinical presentations of acute and chronic osteomyelitis can vary widely and may be difficult to discern from acute vaso-occlusive pain episodes. Patients may report bone pain, difficulty ambulating, edema, skin erythema, and point tenderness to palpation. In chronic osteomyelitis, draining sinus tracts can develop. Providers should have a high index of suspicion and consider dedicated MRI imaging for further evaluation. In a meta-analysis focused on management of septic arthritis in children with SCD, no single laboratory value was able to predict septic arthritis.[242] The only laboratory value that may be helpful in diagnosing osteomyelitis is elevated CRP. However, caution should be exercised when interpreting CRP results given that SCD is an inflammatory disease.

The diagnosis is confirmed by culture of blood or infected bone. Parenteral antibiotics that cover *Salmonella* spp. and *S. aureus* are

TABLE 43.9 **Organ-Related Infection in Sickle Cell Disease**

Primary Sites of Infection	Most Common Pathogen(s)	Other Pathogens	Pathophysiology	Prevention	Management
Septicemia	*Streptococcus pneumonia*	*Haemophilus influenza* type b *Escherichia coli* *Salmonella* spp.	Defective splenic function; deficiency of opsonic antibody	Vaccines[a] Prophylactic penicillin	Empiric intravenous antibiotics for fever
Meningitis	*S. pneumoniae*			Same as for septicemia	
Osteomyelitis and septic arthritis	*Salmonella* spp. *S. pneumonia*	*E. coli* *Proteus* spp. *Staphylococcus aureus*		–	Surgical drainage, intravenous antibiotics
Pneumonia	*Mycoplasma pneumonia* Respiratory viruses	*Chlamydia pneumonia* *S. pneumoniae*		Vaccines[a]	See pulmonary and therapy sections for management of acute chest syndrome

given, and tailored antibiotic therapy is based on culture results. Parenteral antibiotics are continued for 2 to 6 weeks.[242] Surgical drainage or sequestrectomy may be required. Most patients are cured by this approach, but there may be recurrences.[242]

Articular infection is less common and is often caused by *S. pneumoniae*.[241]

Parvovirus B19

The specificity of the parvovirus B19 (see also Aplastic Crises) for erythroid precursor cells, coupled with the accelerated erythropoiesis in hemolytic anemias, leaves sickle cell patients vulnerable to infection by this agent.[243] In SCD, parvovirus infection is a common cause of aplastic crisis, especially in children. It has been reported to cause bone marrow necrosis, ACS, pulmonary fat embolism, hepatic sequestration, glomerulonephritis, and acute nephrotic syndrome.[212–215,244]

Urinary Tract Infections

Patients with SCD are at a higher risk for urinary tract infections and pyelonephritis than the general population. Higher rates of volume depletion and urinary tract obstruction related to infarction or papillary necrosis may contribute to observed rates of infection. Evaluation should include urinalysis, urine culture with sensitivities, renal ultrasonography to assess for ureteral obstruction, as well as pregnancy testing in women of reproductive age. Children notably may lack typical urinary tract symptoms such as dysuria or urinary frequency. *Escherichia coli* is the most common uropathogen and can cause septicemia in these patients. Persistent urinary tract infections may be secondary to renal papillary necrosis. Recent literature has suggested that patients with SCD may have higher rates of asymptomatic bacteriuria although the clinical relevance of this finding remains unclear.[245] All urinary tract infections in this patient population should be considered complicated and duration of antibiotic therapy may range from 10 to 21 days.

Neurologic Complications

Neurologic complications occur in 25% or more of patients with SCD.[246] Neurologic complications include CVAs (consisting of transient ischemic attacks [TIAs], overt and silent cerebral infarction, cerebral hemorrhage), seizures (which can be a presenting feature of CVA), unexplained coma, spinal cord infarction or compression, central nervous system infections, vestibular dysfunction, and sensory hearing loss.[247–249]

Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation[250]

Histopathologic evaluation of large-vessel involvement in SCD shows a pattern of smooth muscle proliferation with overlying endothelial damage and fibrosis. Smaller arterioles and capillaries demonstrate distension, thrombosis, and vessel-wall necrosis.[251,252] Aneurysmal dilatation associated with hemorrhagic stroke occurs at regions of intimal hyperplasia.[252] The vessel wall changes are likely multifactorial in origin related to endothelial injury from high and turbulent flow, RBC adherence, and hypoxia; but in addition, it has been speculated that depletion of NO by the free Hb released through intravascular hemolysis may also play a role.[254] The age-specific pattern of stroke risk in SCD may be related to the higher cerebral flow rates in early childhood.[254] Cerebral thrombosis, which accounts for 70% to 80% of all CVAs in patients with SCD, results from large-vessel occlusion (see Fig. 43.8) rather than the more typical microvascular occlusion of SCD.[253,254] Silent infarcts are thought to result from microvascular vaso-occlusion or thrombosis or chronic hypoxia in the periphery stemming from large-vessel disease.[255] In 30% of patients with SCD, major vessel stenosis results in the formation of friable collateral vessels that appear as puffs of smoke (*moyamoya* in Japanese) on angiography.[256] Moyamoya disease predisposes to thrombotic and hemorrhagic strokes, seizures, and cognitive disability.[257]

The relative risk for stroke is 200 to 400 times higher in children with SCD compared with children without SCD. The prevalence of clinically overt stroke is 11%. Clinically silent infarction detectable by MRI affects 17% to 20% of patients by age 20 years and 53% of adults (21 to 42 years, median age 30 years).[258] Silent infarcts are lesions visible in at least two planes of T2-weighted MRI images and are at least 3 mm in greatest linear dimension.[259] Such lesions are not truly silent and are associated with both neurocognitive and behavioral impairments in patients with SCD. Even in patients without silent or overt cerebral infarction, cognitive functioning can be impaired.[260] Almost 50% of children with “silent” infarcts eventually require lifelong support or custodial care because of neuropsychologic deficits.[261] Whereas infarctive strokes are more common in children and those older than 30 years of age, hemorrhagic stroke tends to occur between ages 20 and 30 years.[52] Intracranial aneurysms are reported in 3% of children and 11% to 15% of adults with SCD. Affected patients will often have aneurysms at multiple sites.[262,263] Aneurysms may require surgical intervention or endovascular coiling if they are rapidly enlarging or result in subarachnoid hemorrhage.

Sickle cell–specific risk factors for CVA include increased cerebral blood flow velocity[264] (discussed further under Primary Prevention of Cerebrovascular Accidents), a history of overt or silent cerebral infarction,[265] nocturnal hypoxemia or sleep apnea,[266] severe anemia, higher reticulocyte counts, lower HbF levels, higher WBC counts, HbSS genotype (rather than HbSC disease or sickle cell–β-thalassemia), prior ACS, migraines, elevated homocysteine levels, as well as "relative" systolic hypertension (i.e., those at the high end of the lower-than-normal range characteristic of SCD).[52,66] Genetic markers of increased risk are the Central African Republic (CAR) haplotype and the absence of α-thalassemia.[253,267] Both small- and large-vessel thrombosis can occur. Increased stroke risk in siblings with SCD suggests that additional genetic factors might be involved. For instance, specific HLA alleles separately correlate with small- versus large-vessel stroke risk as well as VCAM-1 variants.[253]

In addition to these sickle cell–specific predictors of stroke, one must also consider the well-documented modifiable risk factors for stroke that are operational in the general population; these are hypertension, exposure to cigarette smoke (active smoking or passive exposure), diabetes, atrial fibrillation, dyslipidemia, carotid artery stenosis, postmenopausal hormone therapy, poor diet, physical inactivity, obesity, and fat distribution. Less well-documented but potentially modifiable risk factors include alcohol or drug use, oral contraceptive use (especially those containing estrogen), and sleep-disordered breathing.[268]

CVAs are heralded by focal seizures in 10% to 33% of cases and by TIAs in 10%. CVAs are fatal in approximately 20% of initial cases, recur within 3 years in nearly 70%, and are the cause of motor and cognitive impairment in the majority. Intracranial hemorrhage results in the same signs as thrombosis, but in addition, neck stiffness, photophobia, severe headache, vomiting, and altered consciousness may occur. Coma suggests hemorrhage rather than thrombosis. A typical presentation is coma and seizures without hemiparesis. Although the mortality rate may be as high as 50%, the morbidity of survivors is low. Hemorrhage may be subarachnoid, intraparenchymal, or intraventricular, which can be differentiated by angiography. The favorable neurosurgical outcome in subarachnoid hemorrhage caused by ruptured aneurysm justifies an aggressive approach to diagnosis, transfusion, vasodilatory therapy, and surgery.

Primary Prevention of Cerebrovascular Accidents

The overall risk of stroke in pediatric patients with SCD is 1% per year; however, in the subset of patients with transcranial Doppler evidence of a high (>200 cm/s) cerebral blood flow velocity in the internal carotid artery or middle cerebral artery, the stroke risk is in excess of 10% per year (although this is still much lower than the risk of recurrent stroke in a sickle cell patient after a first event, which is approximately 70%). In the Stroke Prevention Trial in Sickle Cell Disease (STOP), 130 children (mean age 8 years) diagnosed as having clinically silent cerebral artery stenosis on the basis of high cerebral flow rates were randomized to receive chronic transfusion therapy with a goal HbS of less than 30% versus observation. Over a period of more than 2 years, the risk of stroke was reduced to less than 1% per year in the transfused group[264] (a risk reduction of >90%). The ability of transfusion to curtail progression of large-vessel stenosis has also been proven with angiography.[269]

Because of the risks of iron overload and allosensitization with chronic transfusion, a randomized controlled trial of withdrawal of transfusion was conducted (STOP 2). This trial evaluated discontinuation of transfusion after at least 30 months in children who had not had an overt stroke and in whom the cerebral flow rates decreased to low risk (<170 cm/s) with transfusion. This study was terminated early because of a high rate of reversion to high-risk TCD flow rates (34%) and stroke (5%) in the patients taken off transfusion compared with the group who continued transfusion.[268]

In children, MRI can also be used to assess stroke risk: 8.1% of children with an asymptomatic MRI lesion versus 0.5% of those with a normal MRI had a stroke during the ensuing 5 years.[265] A randomized trial of MRI-guided prophylactic transfusion (Silent Infarct Treatment Trial) concluded that regular blood transfusion significantly reduced the incidence of cerebral infarction in children with SCA.[270] In adults, MRI or MRA of the brain should be used[65] to assess thrombotic or hemorrhagic stroke risk.

Chronic transfusion is associated with a significant complication rate including alloimmunization and iron overload. Therefore there is a need for alternatives, especially because some patients and physicians believe that the 10% annual stroke risk does not warrant the risks and burdens of chronic transfusion.[250]

The use of HU as upfront therapy for primary prevention of stroke has not been evaluated in randomized trials. However, select children and adolescents may be able to transition to HU following a period of chronic transfusion. In the TWiTCH trial, 121 children on chronic transfusion therapy for at least 1 year were randomized to transition gradually from transfusions to HU or to continue transfusion therapy.[271] The primary endpoint was non-inferiority for TCD velocity at 24 months. The trial was terminated early because the first interim analysis revealed non-inferiority for the primary endpoint. No strokes or silent infarcts were reported. There were 3 TIAs in each treatment arm (5%). Iron levels in the TWiTCH trial were significantly reduced in the HU arm. In addition, liver iron increased from 8.5 to 11.3 mg/g liver weight in the transfusion arm and decreased from 11.3 to 9.5 mg/g liver weight in the HU arm. There are multiple caveats to consider including the relatively short duration of follow up and adherence rates to HU regimens in the study; caution should be exercised when selecting patients for this approach.

The role of aspirin in ischemic stroke prevention in SCD is being evaluated (see Basic Management and Disease Modification).

Other modifiable risk factors for stroke (see Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation) should be identified and treated. Notably, in the general population, hypertension is particularly associated with a risk for hemorrhagic stroke, and effective treatment of hypertension can produce a relative risk reduction of 26% for ischemic stroke and 49% for hemorrhagic stroke.[272] In patients with SCD followed through the Cooperative Study of Sickle Cell Disease, both diastolic and systolic blood pressures were noted to be lower than for matched control participants. Patients with systolic pressures in the higher range for the sickle cell group, even with systolic pressures less than 140 mmHg, had an increased risk of first ischemic stroke (there were insufficient events to make firm conclusions regarding hemorrhagic stroke).[52] Therefore, at a minimum, it seems reasonable to follow population-wide recommendations for blood pressure control in patients with SCD.

Evaluation and Management of Acute Cerebrovascular Accidents

Patients with symptoms and signs of CVA should be evaluated immediately using CT scanning or MRI to distinguish among TIA, cerebral thrombosis, and hemorrhage. In those with hemorrhage, angiography or MRA is indicated after partial-exchange transfusion is performed to avoid complications associated with the injected contrast material. In both thrombosis and hemorrhage, prompt partial-exchange transfusion is performed, and chronic direct transfusion to maintain the HbS level below 30% is instituted to prevent recurrent events (see also Basic Management and Disease Modification) and promote resolution of arterial stenoses.[269]

Secondary Prevention of Cerebrovascular Accidents

The risk of recurrent stroke is approximately 70%, a risk that is reduced to around 13% with chronic transfusion.[273] Although recurrent CVAs during chronic transfusion have been reported, this therapeutic modality provides the best means of preventing recurrence (Fig. 43.10). This treatment also provides incidental protection against pain crises, bacterial infections, ACS, and hospitalization.

Based on the data from STOP 2 (see Primary Prevention of Cerebrovascular Accidents), chronic transfusion is continued indefinitely. This may not be feasible for administrative reasons or because of allosensitization or iron overload for which the patient is unable or unwilling to undergo treatment. In patients with a history of CVA transitioned from chronic transfusion to HU, the recurrent stroke rate remained stable and in the range seen with continued transfusion.[273a]

Per primary prevention, all other identified modifiable risk factors for stroke should be identified and treated.

In patients with moyamoya disease, surgical approaches to therapy, such as extracranial-intracranial bypass, have been useful in improving the perfusion of affected regions of the brain.

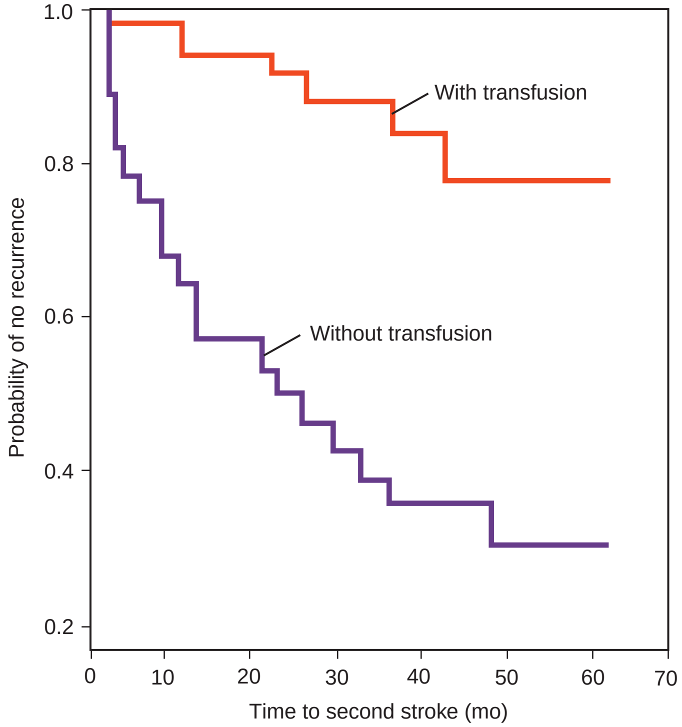

Figure 43.10 COMPARISON OF STROKE RECURRENCE OVER 62 MONTHS IN A TRANSFUSED GROUP AND IN UNTRANSFUSED HISTORICAL CONTROL GROUPS. *(Adapted with permission from Pegelow CH, Adams RJ, McKie V, et al. Risk of recurrent stroke in patients with sickle cell disease treated with erythrocyte transfusions. J Pediatr. 1995;126:896–899.)*

Stem cell transplantation has resulted in stabilization of cerebral vasculopathy,[274] but the risk of a second neurologic event is higher in the peritransplant period, and the mortality rate with this procedure is between 6% and 10%.[274]

Seizures

Seizures occur more commonly among patients with SCD. In one study, 21 of 152 patients in a pediatric clinic had seizures, four of which were related to meperidine therapy. Most had non-focal CT and MRI studies but focal electroencephalographic changes.[275] CVAs are heralded by focal seizures in 10% to 33% of cases. Therefore, seizures in SCD ultimately may be related to the underlying vasculopathy.

Pulmonary Complications

Pulmonary disease is the leading cause of death in patients with SCD.[40] Both acute and chronic pulmonary complications are common; a unifying clinical manifestation is hypoxia.[276] Acute complications include pneumonia and ACS and chronic complications range from PH to chronic thromboembolic disease.

Pneumonia

Pneumonia is defined as chest infiltrates on chest radiography or chest CT scan associated with fever and an identified infectious etiology. The risk for and increased frequency of *S. pneumoniae* infections is discussed under Infections earlier. In addition, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* spp. are also relatively common causes of pneumonia in patients with SCD. Antibiotic therapy for pneumonia or ACS should cover these agents in addition to pneumococcus and *H. influenzae*. When antibiotics are used to treat the ACS, they should cover *S. pneumoniae*, *H. influenzae* type b, *M. pneumoniae*, and *C. pneumoniae*.

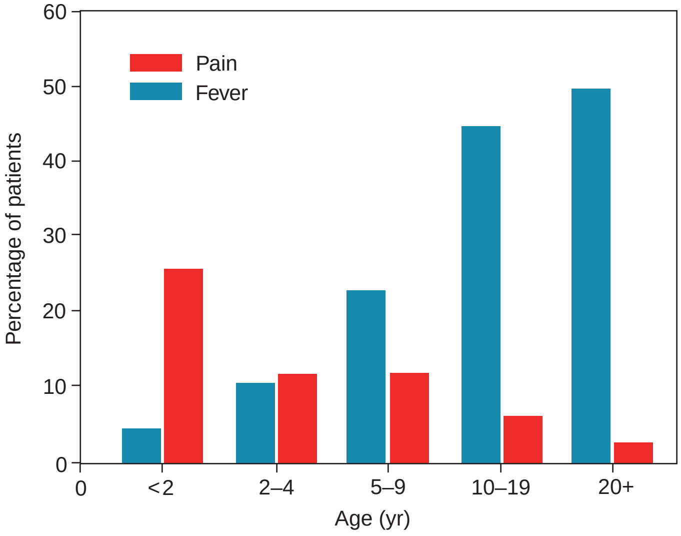

Figure 43.11 AGE-SPECIFIC ASSOCIATED EVENTS WITHIN 2 WEEKS PRECEDING ACUTE CHEST SYNDROME. *(Adapted with permission from Vichinsky EP, Styles LA, Colangelo LH, Wright EC, Castro O, Nickerson B. Acute chest syndrome in sickle cell disease: clinical presentation and course. Cooperative Study of Sickle Cell Disease. Blood. 1997;89:1787–1792.)*

Acute Chest Syndrome

ACS occurs in approximately 30% of patients.[277] ACS is defined as a new segmental (involving at least one complete segment) radiographic pulmonary infiltrate identified on chest radiography or chest CT scan associated with one or more new symptoms, which include fever, chest pain, cough, sputum production, dyspnea, tachypnea, and hypoxia (>2% decrease in SpO_2 [O_2 saturation]) from a documented steady-state value on room air). Risk factors include HbSS genotype, low HbF concentrations, and high steady state Hb and leukocyte values.[277] This entity is included in discussions of SCD because processes other than infection, such as vaso-occlusion, could also lead to pulmonary symptoms, signs, and chest radiographic changes. However, it should be borne in mind that the usual etiology might be both vaso-occlusion and infection simultaneously, and in all cases of ACS, antibiotics should be administered. Many episodes in which common pathogens are not cultured are caused by "atypical" agents (*Mycoplasma*, *Legionella*, and *Chlamydia* spp.), suggesting that antibiotic therapy include agents directed at atypical agents. Pulmonary fat embolus, evidenced by stainable fat in pulmonary macrophages obtained by bronchoalveolar lavage or sputum induction, is found in 44% to 60% of cases of ACS.[278] ACS caused by pulmonary fat embolus is associated with more severe hematologic and clinical abnormalities. A decrease in Hb values and a platelet count less than 200,000 cells per μL in association with neurological symptoms including confusion or sternal pain is highly suggestive of marrow infarction with fat embolism. In adults, the ACS mortality rate is four times higher than in children, largely due to a higher incidence of bone marrow and fat emboli and the presence of other comborbidities.[15,279]

ACS is often preceded by febrile episodes in children and by vaso-occlusive pain crisis in adults (Fig. 43.11).[279] Elevation of serum phospholipase A2 was detected in patients admitted with vaso-occlusive pain crisis 24 to 48 hours before ACS was clinically diagnosed.[280] Pulmonary fat embolus is often preceded by an acute painful episode. ACS should prompt aggressive inpatient management including judicious use of opioid analgesics to prevent respiratory compromise, supplemental oxygen therapy with pulse oximetry monitoring, frequent use of bedside incentive spirometry in conjunction with respiratory therapy and empiric antibiotics, typically a cephalosporin and macrolide. All adult patients should receive thromboprophylaxis with unfractionated heparin or low-molecular-weight heparin (LMWH) as per institutional guidelines unless contraindicated. Simple or exchange transfusion are the mainstays of acute treatment of ACS; the decision to pursue exchange transfusion depends on the clinical severity and progression of ACS as well as hemoglobin levels. Some patients have a rapidly progressive course associated with a precipitous decrease in arterial oxygen tension within 24 hours of developing respiratory symptoms and multiorgan failure; they may require intensive care treatment. Repeat chest imaging with plain films and serial blood gas measurements to assess arterial oxygenation status may be necessary in cases of rapid respiratory decline. If there are clinical signs of respiratory distress or when arterial oxygen tension cannot be maintained above 70 mmHg with inhaled oxygen, partial-exchange transfusion is indicated and mechanical ventilation may be required.

In patients with pneumonia or chest syndrome, antibiotics should cover *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, *H. influenzae*, and *Legionella* spp.

Pulmonary Hypertension

PH affects approximately 6% to 11% of patients with SCD and is defined as a mean pulmonary artery pressure ≥25 mmHg at rest diagnosed by right heart catheterization.[281–284] Sickle-related PH is an independent risk factor for mortality with an approximate 40% six-year mortality according to one study of 531 patients.[35,285] PH in SCD is classified as multifactorial; some patients have hemodynamics consistent with pulmonary arterial hypertension, while others have features of PH related to chronic thromboembolic disease or left-sided heart disease. There does not appear to be an association with the occurrence of ACS,[282] emphasizing that the pathophysiology of these two conditions may differ in some key features. The pathophysiology may involve thrombi in large and small arteries,[286,287] cardiac decompensation from progressive anemia, and potentially reversible increases in vascular tone from NO depletion and medial and intimal hypertrophy.[287] The recognition that PH is a feature of hemolytic syndromes other than sickle cell and that markers of hemolysis correlate with the risk of PH supports the idea that depletion of NO through scavenging by free Hb may have an important role in the pathophysiology of this disease.[283,288]

The association with early death and the emerging availability of candidate treatments suggest that efforts should be made to diagnose this condition in all patients with SCD.[283,288] The diagnosis is challenging in patients with SCD because of the many potential causes of dyspnea, exercise intolerance, and fatigue.[289] The feasibility of an echocardiogram-determined TRJV measurement of 2.5 m/s to make the diagnosis was suggested by selective cardiac catheterization in a cohort of 195 patients[281]; however, the sensitivity and specificity of this test may have limitations.[288] Transthoracic echocardiographic estimates of pulmonary pressures are substantially less accurate than right heart catheterization, with a positive predictive value of approximately 31%.[290] However, risk stratification based on TRJV helps to guide clinical decision-making in patients with SCD. In adult patients aged 18 and older, echocardiography screening should be considered in patients with respiratory symptoms including exertional dyspnea, TRJV of 2.5 m/s or greater on prior echocardiogram, thromboembolic disease, or severe hemolytic anemia. Additional testing including ventilation perfusion scanning and the 6-minute walk test (6MWT) can aid in the diagnostic work-up of suspected PH. Elevations in BNP levels have been correlated with an increased TRJV and risk of early death in SCD cohorts. All patients with suspected PH should be referred to a pulmonologist for further evaluation and consideration of right heart catheterization.

The optimal therapy for PH secondary to SCD is not known.[289] Management of adults with sickle-related PH includes supplemental oxygen therapy for those with low oxygen saturation, diuretics to treat right ventricular overload, long-term anticoagulation in patients with evidence of prior or current thromboembolic events with low bleeding risk, as well as HU and/or transfusions to maintain adequate Hb levels, decrease hemolysis, and reduce the frequency of VOC. Targeted agents including endothelin receptor and prostanoid pathway agonists may be considered in select patients.

In a 16-week, double-blind, placebo-controlled trial of sildenafil to treat patients with SCD with increased TR-jet velocity and a low exercise capacity, sildenafil increased hospitalization rates for pain without evidence of improvement in TR-jet velocity or BNP levels.[291] As such, sildenafil is relatively contraindicated in patients with sickle-related PH.

Other Pulmonary Complications

Other findings include restrictive and obstructive lung disease and hypoxemia.[292] High-resolution, thin-section CT scanning of the lungs may show chronic interstitial fibrosis. Airway hyperreactivity occurs in nearly two-thirds of children with SCD not diagnosed as having asthma. Thirty-six percent of 53 children with SCD were found to have sleep-related upper airway obstruction, 16% had hypoxemia, and all 15 who underwent adenotonsillectomy improved symptomatically and had improved hypoxemia.[293] Sleep apnea may be associated with exacerbations of painful episodes and strokes. Pulmonary function measurements should be obtained as baseline data and patients with signs or symptoms suggestive of sleep apnea should undergo formal full-night polysomnography (PSG). This is especially important in patients who chronically require opiate therapy and/or sedative medications which can induce central apnea.

Hepatobiliary Complications

"Sickle hepatopathy" is an umbrella term that encompasses the broad clinical spectrum of liver disease that is observed in patients with SCD. It occurs predominantly in patients with HbSS disease but can also be seen in HbSC or HbSβ-thalassemia disease. Hepatobiliary complications in patients with SCD include cholelithiasis, cholecystitis, acute hepatic cell crisis, acute hepatic sequestration crisis, and sickle cell intrahepatic cholestasis.[294] Chronic transfusion places patients at risk for hepatitis infection and transfusional hemosiderosis. Nontransfusion-related hepatic hemosiderosis can also be seen. The prevalence of cirrhosis has been reported to be as high as 30% in SCD autopsy case series.[295] In rare instances, patients with SCD may present with decompensated chronic liver failure necessitating liver transplantation.[296]

The serum bilirubin level is higher in SCA (HbSS or HbSβ^0-thalassemia) than in HbSC disease or HbSβ$^+$-thalassemia as a result of a greater hemolytic rate. The level rises after the first decade, possibly as a result of chronic hepatobiliary dysfunction. Total bilirubin concentrations are usually less than 6 mg/dL (102.6 μmol/L) but may increase beyond this threshold during sickle hepatic crises.[297] Total bilirubin levels are also influenced by co-inheritance of the promoter variant in the *UGT1A1* gene, also referred to as Gilbert syndrome.[2] The AST and alanine aminotransferase (ALT) levels are often elevated, particularly in adult patients with SCA. Serum AST increases during hemolysis and correlates with LDH whereas acute increases in ALT levels may reflect hepatocyte injury. Alkaline phosphatase levels are elevated in all genotypes. Minor abnormalities in liver function tests may reflect ongoing hemolysis but significant increases in conjugated bilirubin, decreased synthetic function, and low albumin levels are suggestive of intrinsic liver disease. Concurrent autoimmune liver disease has been observed in SCD cohorts and a liver autoantibody screen (antinuclear antibodies, anti-smooth muscle antibodies, anti-liver kidney microsomal antibodies) should be performed in select cases. MRI imaging of the abdomen which can quantify hepatic iron (R2-MRI or T2*) should be performed.[296] Percutaneous liver biopsy is associated with a high risk of severe complications and death in patients with acute hepatic syndromes and in general should be avoided.[298]

Cholelithiasis and Cholecystitis

The prevalence of pigmented gallstones in SCD is directly related to the rate of hemolysis.[299] In SCA, gallstones occur in children as young as 3 to 4 years of age and are eventually found in approximately 70% of adult patients. Co-inheritance of a genetic variant in the promoter of *UGT1A1* gene greatly influences level of bilirubin and age of onset of gallstones. Some have recommended the surgical removal of asymptomatic gallstones to avoid subsequent difficulty in distinguishing gallbladder pain from acute painful episodes. The management of acute cholecystitis and ascending cholangitis requires broad-spectrum antibiotic therapy covering *Salmonella* and anaerobic organisms; elective cholecystectomy should be performed once acute complications resolve. This approach has become more feasible with the availability of laparoscopic cholecystectomy.[300] Laparoscopic cholecystectomy is associated with a shorter hospital length of stay and lower rates of postoperative complications, although it does not reduce the risk of sickle cell–related complications compared with open cholecystectomy. The role of cholecystectomy in patients with asymptomatic cholelithiasis remains controversial.[295]

Acute Hepatic Cell Crisis

Acute hepatic cell crisis occurs in approximately 10% of patients and presents with tender hepatomegaly, worsening jaundice, and fever.[294] The likely etiology is hepatocellular cell ischemia. The AST and bilirubin are elevated, but rarely above 300 IU/L and 255 μM, respectively. The serum total bilirubin concentration is usually less than 15 mg/dL. This syndrome usually resolves within 3 to 14 days with supportive care alone but can progress to liver failure and fatal outcomes, therefore patients should be monitored closely and exchange transfusion initiated if they show signs of progressive liver dysfunction (e.g., increasing AST).

Acute Hepatic Sequestration Crisis

The pathophysiology of acute hepatic sequestration involves sequestration of sickled erythrocytes in the liver. Patients present with right hypochondrial pain, acute hepatic enlargement, and a dramatic fall in Hb concentration. Management includes supportive care and conservative transfusions in the setting of acute anemia. Providers should target the minimal acceptable Hb level with transfusion to prevent hypovolemia or organ dysfunction; rare cases of auto-transfusion have been reported with resultant hyperviscosity.[301]

Intrahepatic Cholestasis

The most severe hepatic complication encountered in SCD patients is acute sickle cell intrahepatic cholestasis which is rare but fatal. Widespread sickling within sinusoids induces hepatic ischemia and injury. This results in severe hyperbilirubinemia (predominantly conjugated) with fever, right upper quadrant pain, and leukocytosis.[302] Total serum bilirubin levels may be markedly elevated and levels of 273 mg/dL have been reported in the literature; transaminase levels can be in the thousands. Intrahepatic cholestasis is accompanied by renal failure and coagulopathy.[303] Evidence of progressive liver dysfunction should prompt consideration of acute hepatic cell crisis and exchange transfusion to maintain the HbS percentage less than 30%.

Hepatitis C Infection

Chronic hepatitis C virus (HCV) infection in SCD occurs with a prevalence that is related to the number of transfusions received; it may be a leading cause of cirrhosis. With improved screening, the likelihood of acquiring new HCV infection with blood transfusion in the United States is now extremely rare (approximately 1:1,900,000 units). There have been marked improvements in therapies for chronic hepatitis C infection demonstrating viral eradication rates of over 95% and most patients can receive ribavirin-free drug regimens.[304,305] Nucleotide/nucleoside analogs can be implemented to treat chronic hepatitis B although the prevalence of this infection in SCD cohorts remains low.[306] Liver transplantation has been used successfully as therapy for this complication.[307] Experience with liver transplantation in SCD patients is increasing although early studies demonstrated poor outcomes, with mortality rates of approximately 60% at 1 year post-transplant.[295,296] Later studies have shown decreases in transplant-related mortality as a result of improved patient selection and perioperative management practices.

Obstetric and Gynecologic Issues

Gynecologic complications (delayed menarche, dysmenorrhea, ovarian cysts, pelvic infection, and fibrocystic disease of the breast) are more common in women with SCD. Pregnancy entails increased risks to the mother and child compared with the general population.[308]

Pregnancy

Pregnancy in patients with SCD is associated with increased risks to both the mother and fetus, although these risks are not so great as to prohibit continuation of pregnancy.[309,310] The fetal complications of pregnancy, most of which are related to compromised placental blood flow, are the increased incidence of spontaneous early abortion, intrauterine growth retardation, low birthweight, and fetal death. Maternal complications include increased rates of painful episodes, severe anemia caused by iron or folate deficiencies, exaggeration of the physiologic "anemia of pregnancy," increased infections (urinary tract infections, pneumonias, endometritis), venous thromboembolism, preeclampsia and eclampsia, and death.[310] It is controversial whether the degree of anemia predicts the birth of babies with low birthweight. The occurrence of a perinatal death in a previous pregnancy and the presence of twins in the present pregnancy are two major risk factors for an unfavorable outcome. The course of pregnancy is more benign in HbSC disease than in SCA, the latter is more likely to have painful crises and blood transfusions, and the overall rate of maternal and fetal complications in mothers with SCD is higher compared to mothers without SCD.[311]

Better fetal and maternal outcomes in recent years are largely attributable to generally improved antenatal and obstetric care. Patients should be followed in a high-risk obstetric clinic in addition to the hematology clinic and receive the usual vitamin, mineral, and folate supplements. A high-calorie, high-protein diet can be considered. There is no specific therapeutic or preventive treatment for intrauterine growth retardation. Some experts recommend prophylactic transfusion, but a large controlled study showed no improvement in fetal outcomes from this management option, although maternal symptoms are reduced.

Women with SCD may be receiving disease-modifying therapies and current guidelines recommend discontinuation of HU several months before conception or at time of pregnancy. Exposure to HU has been reported in less than 100 human pregnancies and an increase in major congenital defects was not observed but has been reported in animal studies.[312] Fetal risks from L-glutamine, voxelotor, and crizanlizumab are unknown and as such these agents should be avoided during pregnancy. Folic acid supplementation should be continued. Medications to manage renal medical disease and hypertension, including ACE inhibitors and ARBs, should be discontinued given known teratogenic effects and alternative antihypertensive agents should be instituted. Chelation should be discontinued once pregnancy occurs unless there are extenuating circumstances with severe iron overload given the potential risk for congenital abnormalities. Close monitoring for VTE is necessary throughout pregnancy; women should receive low-molecular-weight heparin for thromboprophylaxis when hospitalized.[313]

An individualized transfusion plan should be developed for pregnant patients highlighting indications for acute and chronic transfusion regimens. In addition to the usual indications for transfusion therapy in SCD, transfusion therapy is indicated for patients with cardiac or respiratory compromise, in preparation for cesarean section, preeclampsia, twin pregnancy, ACS, Hb levels more than 20% below steady state or less than 5 g/dL, and previous history of perinatal mortality. If the Hb is between 8 and 10 g/dL and transfusion is indicated for any of the reasons above, partial exchange should be performed (e.g., phlebotomy of 400 to 500 mL and transfusion of 2 units of packed RBCs).[309] The type of delivery does not appear to represent a problem, and both spontaneous delivery and cesarean section are well tolerated.

Some experts advise that hypertonic saline injections are contraindicated for elective termination of pregnancy because of the risk of sickling-induced vaso-occlusion. There are anecdotal reports of a higher incidence of acute painful episodes after therapeutic abortion; inpatient intravenous hydration before and for the 24 hours after the procedure is recommended.

Prenatal Diagnosis

All pregnant women with SCD should be offered prenatal counseling, including hemoglobinopathy testing for their partner. The genotype of the mother should be established and testing of the partner should

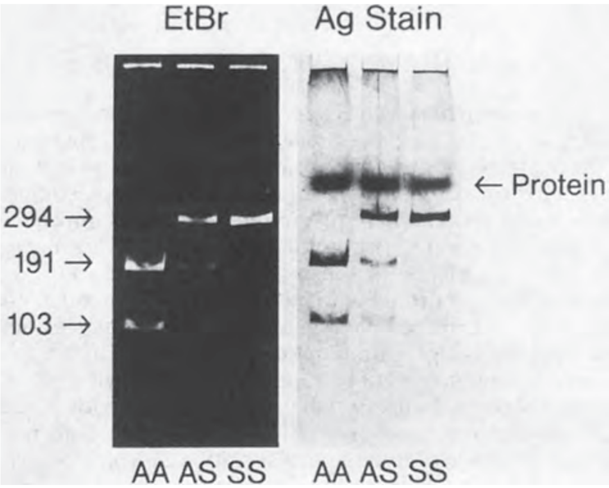

Figure 43.12 POLYMERASE CHAIN REACTION (PCR)–BASED RESTRICTION ANALYSIS FOR THE SICKLE CELL GENE. The genotypes of the DNA samples tested are shown *below*. The size in base pairs for the undigested PCR product and the products resulting from Oxa Nl are shown at the *left* in base pairs. The fragments from normal β-globin DNA (AA) shows complete Oxa Nl cleavage, from sickle cell trait DNA (AS) shows partial cleavage, and from sickle cell anemia (SS) shows no cleavage. *Ag stain*, Silver stain; *EtBr*, ethidium bromide.

include a CBC and hemoglobin electrophoresis.[313] One large survey found that parents at risk for having a child with SCD were interested in prenatal diagnosis and would consider termination of pregnancy for an affected fetus.[314] Community acceptance of reproductive genetic services depends on the effectiveness of education and counseling but currently the ability to predict severity of disease is very limited.

Fetal DNA samples are obtained by chorionic villus sampling at 8 to 10 weeks' gestation. Polymerase chain reaction (PCR)–based methods for detecting the sickle gene include restriction analysis (Fig. 43.12), allele-specific hybridization, reverse dot blotting, and allele-specific fluorescence PCR. PCR-based diagnosis for HbSC disease is possible using specific molecular methods for detecting the HbC gene, and the diagnosis of HbSβ-thalassemia can be made using reverse dot-blot methodology to screen the many African American β-thalassemia mutations, as well as the HbS and HbC mutations, in a single hybridization reaction. Given current DNA technology, it is far more efficient to directly sequence the beta globin genes. Currently, fetal DNA is obtained from amniocentesis or chorionic villus sampling; although these techniques increase the risk of fetal miscarriage, a meta-analysis concluded that the procedure-related risks are much lower than quoted and less than 0.5%.[315] Non-invasive prenatal diagnosis avoids this risk using cell-free fetal DNA in maternal plasma but the accuracy of this technique is not at a clinically applicable stage. Some couples want to avoid having a fetus with SCD but find PND and selective termination unacceptable. Preimplantation genetic diagnosis involves the use of in vitro fertilization techniques to generate 5 to 15 embryos; at the eight-cell stage, one embryonic cell can be removed and tested for sickle alleles; it is then possible to implant only embryos without SCD. It is currently, however, a difficult, stressful, and expensive procedure.

Reproductive Health

Reproductive healthcare should be provided to all adolescent and adult females with SCD. All women should undergo age-appropriate gynecologic and cancer screening on an annual or semi-annual basis, including breast and pelvic examination with pap smear testing. Family planning should be discussed with patients who desire to conceive children with early referral to reproductive endocrinology given the high incidence of infertility. HU and chronic transfusion regimens may support fertility by reducing sickled erythrocytes and resultant organ dysfunction.[313]

CASE 3: VENOUS THROMBOEMBOLISM IN SICKLE CELL DISEASE

A 28-year-old female with HbSS disease and previous history of unprovoked bilateral pulmonary emboli (PE) presented with the acute complaint of worsening dyspnea after recent plane travel. At the time of the initial PE event several years prior, evaluation with compression ultrasonography of the lower extremities was negative for deep venous thrombosis (DVT). Transthoracic echocardiogram demonstrated a borderline TRJV of 2.8 m/s without evidence of right heart strain physiology. After the standard period of anti coagulation, the patient discontinued chronic anticoagulation with warfarin due to inconvenience and cost of INR laboratory monitoring. She also desired contraception and was placed on an oral hormonal contraceptive containing estrogen. On evaluation, intake vitals including oxygen saturation on room air were within normal limits. Cardiopulmonary auscultation was unrevealing. Physical assessment of the lower extremities did not demonstrate stigmata of acute DVT.

Question 1: What is your provisional diagnosis and what tests would you perform?

Exclude pulmonary embolism and/or DVT given the history of recent plane travel. A CTPA was performed which revealed a subsegmental filling defect in the right upper lobe. Lower extremity duplex ultrasonography was negative for DVT.

Question 2: What is the next step in evaluation and management?

Given the patient's prior history of venous thromboembolism (VTE), it was recommended to resume therapeutic anticoagulation on an indefinite basis. Initiate DOAC therapy and counsel patient on the risks of estrogen-containing contraceptives in relation to VTE.

She discontinued her oral birth control pill and was advised to consider alternative birth control methods in the future, including an intrauterine device (IUD).

VTE is a frequent and important clinical complication encountered in adults with SCD. SCD is a known hypercoagulable state associated with both coagulation and platelet function abnormalities. The diagnostic value of D-dimer screening for VTE in SCD is limited given baseline elevations secondary to chronic inflammation. Other screening tools, including the modified Geneva score, are of limited clinical utility in SCD. Heparin, vitamin K antagonists, and DOACs are all effective agents in the treatment of VTE in SCD patients. The optimal treatment duration of confirmed pulmonary thrombosis in SCD is not known, but the ongoing thrombotic risk and high rate of recurrence has led to the practice of lifelong anticoagulation after a first-time PE in SCD patients without contraindications or increased bleeding risk. Recurrent PE is a significant risk factor for chronic thromboembolic pulmonary hypertension (CTEPH).

In patients who desire contraceptive methods to prevent pregnancy, non-estrogen-containing intrauterine devices should be considered. Although depot injections of medroxyprogesterone (Depo-Provera) given every 3 months may be safe with regard to stroke risk,[316] there is a risk of bone loss, a consideration in patients with SCD given their propensity to skeletal complications. Oral contraceptives containing low doses of estrogen can be considered with no clear evidence of increased stroke demonstrated to date, although the patients' overall stroke risk should be taken into consideration. Another caution with low-dose estrogen oral contraception is the risk of contraceptive failure with less than excellent compliance. There may be risks to contraception, but this must be weighed against the risks of unintended pregnancy (see Case 3).

Renal Complications

Renal dysfunction attributed to SCD is generally referred to as sickle cell nephropathy and is a diagnosis of exclusion. CKD occurs in as many as one-fourth to one-third of adults with SCD.[317] The development can be insidious and a screening program incorporating blood pressure monitoring, urinalysis with examination of the urine sediment, spot urine albumin-to-creatinine ratio performed annually, and metabolic panels performed at routine intervals should be instituted by no later than 10 years of age.[318,319] Renal imaging with ultrasound should be performed in patients with a significant unexplained decline in renal function, hematuria, or symptoms suggestive of urinary obstruction. Patients receiving iron chelation may require more frequent monitoring of renal function as deferasirox and deferoxamine are associated with nephrotoxicity.

Hypertension, proteinuria, hematuria, worsening anemia, and nephrotic syndrome reliably predict progression to renal failure, which are clinical indices to pay attention to because the serum creatinine may be misleading. In patients with SCA, serum creatinine is a poor measure of renal function due to an increased proximal tubular secretion of creatinine, and if available, Cystatin C should be used as it is freely filtered by the glomerulus, and not secreted by the renal tubules. Thus, patients may have a significant decline in renal function before it is detectable by measuring creatinine clearance.[320] The mean age at presentation with end-stage renal disease is 41 years.[321]

In infants and young children, there is increased glomerular pressure with compensatory renal hypertrophy, glomerular hyperfiltration, and impaired urinary concentrating ability.[322] Glomerular hyperfiltration is defined as an estimated glomerular filtration rate (eGFR) above gender-specific thresholds (e.g., >130 mL/min/1.73 m^2 for females and >140 mL/min/ 1.73 m^2 for males). These changes often persist into young adulthood but glomerular hyperfiltration is subsequently followed by a decline in GFR over the ensuing years. Serum creatinine levels are low in all genotypes until age 18 years, when young men experience a rise, apparently related to increasing muscle mass. Creatinine levels increase with age in all genotypes, presumably because of declining renal function. Cystatin-based methods for estimating GFR may be more accurate when assessing renal function although such an approach has yet to be validated for routine testing.

Other risk factors for the development of chronic renal failure include the presence of albuminuria, low HbF, and chronic NSAID treatment.[323] The severity of hemolysis impacts renal impairment as measured by proteinuria or eGFR.[324] Thus, it is not surprising that co-inheritance of alpha-thalassemia protects against albuminuria.[325] Variants in the *APOL1* gene, which encodes apolipoprotein L1, have also been associated with renal disease in individuals with SCD.[326]

Episodes of acute renal failure requiring intermittent HD may occur in the setting of vigorous hemolysis, hypovolemia, sepsis, hepatorenal syndrome, cardiac failure, renal vein thrombosis, and rhabdomyolysis. These patients typically recover renal function although cumulative insults result in progressive renal insufficiency. In general, nephrotoxic medications such as NSAIDs, aminoglycoside antibiotics, and radiocontrast used for contrast-enhanced imaging exams should be administered judiciously. Patients should be counseled to avoid chronic use of NSAIDs in over-the-counter medications for pain.

It is important to remember that the SCD population at risk of developing sickle nephropathy (SCN) is also at risk of other diseases that affect the kidneys such as lupus nephritis, blood-borne viruses, and various forms of glomerulonephritis, and that there is no pathognomonic sickle renal phenotype. Not only may these diseases be managed differently to SCN, but they may also influence the prognosis of SCN when they co-exist, and thus need to be excluded. Nephropathies that affect patients with disease include nephrotic syndrome, focal segmental glomerulonephritis (FSGS), and SLE glomerulonephritis which disproportionally affect those of African American ancestry, all of which contributes to end stage renal failure. Once eGFR falls below 40 mL/min/1.73 m^2, the subsequent rate of decline can be rapid, and patients should be offered peritoneal or HD and renal transplantation if eligible.[318]

The renal medulla with its unique hyperosmolar and acidotic environment, together with the low oxygen tension and low-flow state in medullary vasa recta, create optimal conditions for HbS polymerization. Individuals with sickle cell trait have a defect in concentrating urine (hyposthenuria); other renal manifestations encountered in sickle cell trait individuals include albuminuria and hematuria.[327]

Renal Endocrine (Erythropoietin) Deficiency

This is discussed under Basic Management and Disease Modification.

Gross Hematuria

Hematuria may result from microthrombi formation in the peritubular capillaries of the renal medulla or from frank papillary necrosis. Episodes of hematuria occur in approximately 6% of children with SCD and in individuals with sickle cell trait.[328] For gross hematuria, diagnostic evaluation includes urinalysis, culture, and renal ultrasound to evaluate for papillary necrosis, renal stones, and other renal pathology. A much rarer cause of hematuria is renal medullary carcinoma (RMC), an aggressive malignancy found almost exclusively in young Black patients with sickle cell trait.[329] Significant hematuria may resolve with high urinary flow through oral hydration and bed rest. Hematuria that lasts longer than 1 to 2 weeks and results in need for transfusion may require maintenance of high urinary flow using a combination of hypotonic fluids, loop diuretics, and urinary alkalinization using sodium bicarbonate and acetazolamide. These therapies are aimed at changing the acidic, hypertonic environment of the renal medulla that favors erythrocyte dehydration, increased HbS concentrations, and HbS polymerization. If bleeding persists for 72 hours despite these measures, then alternative treatment should be considered. These may include oral urea,[330] ε-aminocaproic acid, and vasopressin. Embolization or nephrectomy should be reserved for prolonged, life-threatening cases of hematuria that require multiple transfusions.

Increased hematuria can also be seen as a consequence of DHTR (discussed in Exacerbations of Anemia).

Papillary Necrosis

Papillary necrosis is most often detected incidentally by imaging or microscopic examination of urine in asymptomatic patients. Renal ultrasound typically demonstrates increased echogenicity of the inner medulla and, in more advanced cases, a filling defect in the area of the medullary tip.[328] CT of the abdomen may be pursued for definitive diagnosis. Sloughed papilla may cause ureteral obstruction and urinary tract infection. In addition to broad-spectrum antibiotics, this occurrence requires emergent relief of the obstruction with a retrograde ureteral stent or placement of a percutaneous nephrostomy tube. NSAIDs should be avoided in patients with papillary necrosis. Otherwise, treatment is as for hematuria.

Proteinuria

Proteinuria can be detected in some patients from late childhood; it is much more prevalent in patients with SCA (HbSS and HbSβ^0-thalassemia), it increases with age and in one cohort, proteinuria was identified in greater than 60% of SCA patients over 45 years of age.[324] Severity of hemolysis correlates with proteinuria, hence co-inheritance of alpha-thalassemia which is associated with reduced hemolysis protects against albuminuria.[324,325] Proteinuria can progress to nephrotic syndrome when proteinuria is accompanied by hypoalbuminemia, edema, and hyperlipidemia. Treatment in adults should be initiated with an ACE inhibitor or ARB when there is persistent urine protein ≥300 mg/day and when the urine protein to creatinine ratio (uPCR) is 50 to 100 mg/mmol (>884 mg/g), which is equivalent to urine protein ≥1000 mg/day. Close monitoring of the blood pressure is essential to avoid hypotension.[318] ACE inhibitors or angiotensin receptor blockers (ARBs) slow the progression of proteinuria in sickle proteinuria, and there is increasing evidence that ACE inhibitors and ARBs may slow or halt the progression of proteinuria to nephrotic syndrome and renal failure.[331,332] Angiotensin II inhibitors are being studied for a potential role in decreasing sickle cell–related proteinuria and renal function deterioration.

Hyposthenuria and Other Abnormalities of Tubular Function

The inability to maximally concentrate urine (hyposthenuria) in response to water deprivation is an early finding of sickle cell

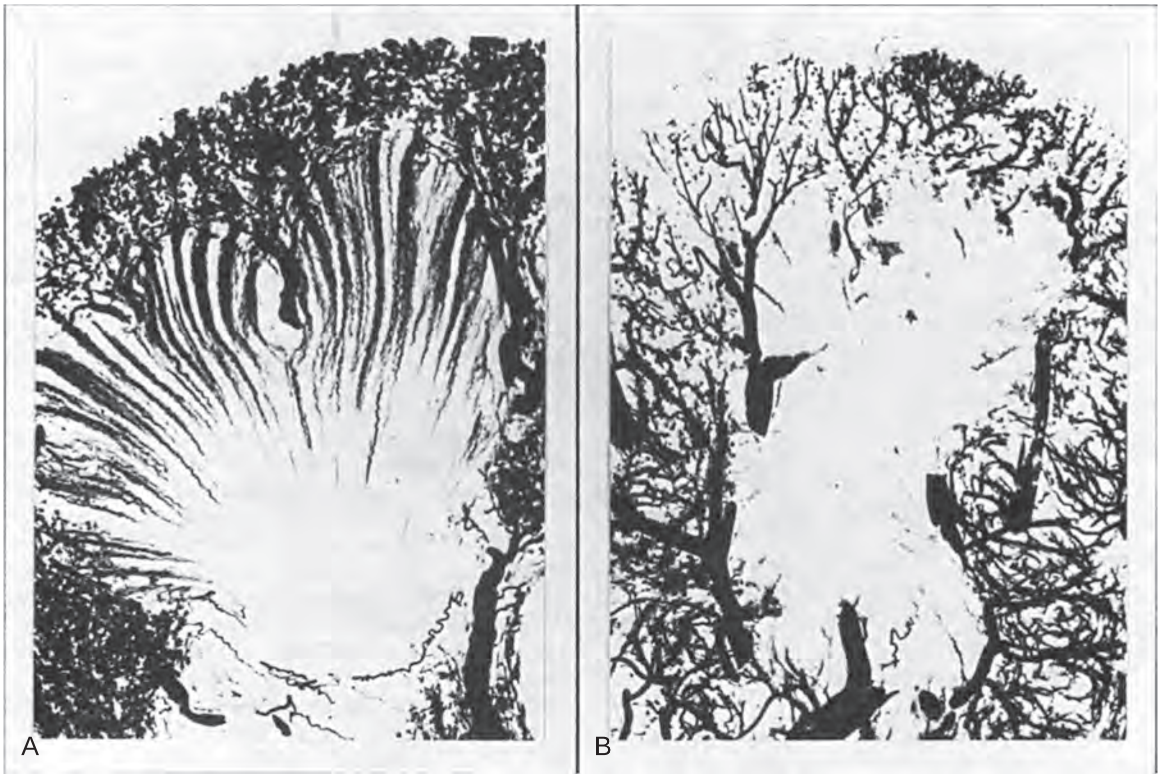

Figure 43.13 Postmortem microangiographic studies of the vasa recta in a normal individual (A) and a patient with sickle cell anemia (B). *(Reproduced with permission from Elsevier. From Statius van Eps LW, Pinedo-Veels C, de Vries GH, de Koning J. Nature of concentrating defect in sickle-cell nephropathy. Microradioangiographic studies. Lancet. 1970;1:450–452.)*

nephropathy. Both sickle cell trait and SCD patients may be affected. Hyposthenuria is the cumulative result of recurrent microinfarcts in the vasa recta caused by sickling (Fig. 43.13). When water deprived, these patients cannot maximally concentrate their urine and develop hypovolemia and dehydration.

Other abnormalities of renal tubular dysfunction found in SCA include an incomplete form of distal renal tubular acidosis with hyperchloremic metabolic acidosis and hyperkalemia.[333] The hyperkalemia may respond to oral sodium bicarbonate.

Enuresis

Enuresis, or nighttime involuntary bedwetting, is common in pediatric SCD patients and may persist into young adulthood. Hyposthenuria, sleep-disordered breathing, and psychological stress may contribute. The evaluation and treatment of this disorder is similar to that of non-SCD patients; behavioral techniques including bed alarms may be helpful is some cases.

Urinary Tract Infections

Urinary tract infections and pyelonephritis are discussed under infectious complications.

Renal Medullary Carcinoma

Sickle cell trait has been reported to be associated with RMC, which is a rare, highly aggressive non-clear-cell renal cancer.[334] It is almost twice as common in men compared to women and the onset is typically in early adulthood.[329] The clinical presentation may include gross hematuria, abdominal or flank pain, or significant weight loss. The disease may be metastatic at diagnosis, and the overall prognosis is poor. There is a weak association of RMC with HbSC disease but no identified association with SCA. The reason for these patterns of disease remain unknown.

Priapism

Priapism is a condition that is characterized by a sustained erection that does not result from sexual desire and is not relieved by sexual activity.[335] Stuttering priapism is a separate entity that is characterized by multiple, brief episodes of sustained unwanted erection. It has been reported to affect 6.4% to 42% of boys and men with SCD[336] and can also occur in sickle cell trait. Its peak frequencies are between ages 5 and 13 years and 21 and 29 years. Priapism is most likely to develop in patients with lower HbF levels and reticulocyte counts, increased platelet counts, and the HbSS genotype. Priapism caused by SCD is usually ischemic, or low-flow, priapism. High-flow priapism is caused by unregulated arterial flow and can be distinguished from low-flow priapism by a blood gas obtained from the corpora. Most likely, priapism begins with a physiologic erection. The relative stasis of blood within the corpora leads to a decrease in oxygen tension and development of acidosis, predisposing to HbS polymerization in the corporal sinusoids, venous occlusion, and low-flow priapism. Pain develops as the corpora become increasingly ischemic after approximately 4 hours of erection. In a minority of patients, usually postpubertal, the engorgement also affects the corpus spongiosum and glans. The mild acidosis that accompanies hypoventilation during sleep may also contribute to the pathophysiology. Impotence is the primary complication of priapism, although some patients with a history of multiple episodes of priapism and significant corporeal fibrosis may report adequate erections and maintain active sex lives. Corporeal ischemia during priapism may induce local inflammation, causing the fibrosis responsible for impotence.

The goal of treatment is to relieve priapism and maintain potency. Patients should be educated to seek medical attention for unrelenting erection of more than 2 hours' duration. Detumescence within 12 hours is optimal to retain potency. After 72 hours, impotence is more likely. The strategy is prompt initiation of supportive medical therapy with intravenous hydration and analgesia and involvement by a urology consultant if the priapism persists for more than 4 hours; aspiration of blood from the corpora with or without irrigation, and injection of an α-adrenergic agonist should be considered (Guidelines of the American Urological Association, https://www.auanet.org/education/guidelines/priapism.cfm). If priapism persists 12 hours, options include partial-exchange transfusion to reduce the HbS level to less than 30% with a total Hb of less than 10 g/dL or irrigation as outlined earlier. The latter procedure is less effective after 36 hours of priapism. Irrigation should be performed using penile anesthesia (dorsal nerve block; circumferential penile block; or subcutaneous, local, penile shaft block). All irrigation in boys should be performed under conscious sedation. There is anecdotal evidence for the use of hydralazine to treat acute priapism.[337]

Preventing recurrent priapism is an important component of management. Strategies include HU administration; chronic transfusion; the antiandrogen bicalutamide[335,338]; self-administration of the α-adrenergic agent etilefrine orally and for episodes lasting over 1 hour, by intracavernous injection; and monthly administration of intramuscular gonadotropin-releasing hormone analogue.[339,340] Prophylactic pseudoephedrine (Sudafed) appears beneficial in preventing recurrent mild episodes. Nocturnal desaturation due to sleep disorder breathing can contribute to priapism, and patients with a history of priapism should undergo an overnight sleep study and be managed accordingly.

Surgical creation of shunts is reserved for severe cases resistant to the above interventions. As many as 45% of patients who have priapism develop some degree of impotence.[341] When impotence persists for 12 months, a semirigid penile prosthesis may be implanted.

Ocular Complications[342]

The retina is particularly vulnerable to vaso-occlusion, and annual retinal examination is part of routine health care maintenance for patients with SCD. Superficial retinal hemorrhages have a pink "salmon patch" appearance. Deeper retinal hemorrhages have a "black sunburst" appearance. Other manifestations of sickle cell retinopathy include iridescent spots, retinal neovascularization, and retinal detachment. More subtle signs of sickle cell retinopathy are optic nerve head vascular changes, vascular tortuosity, macular changes (e.g., microaneurysms and vascular loops), and peripheral arteriovenous anastomoses. Other ophthalmologic complications are anterior chamber ischemia, tortuosity of conjunctival vessels, retinal artery occlusion, and angioid streaks. Sickle cell retinopathy is best seen by fluorescein angiography (Fig. 43.14). The earlier onset and greater frequency of proliferative retinopathy in HbSC disease and HbSβ^+-thalassemia compared with HbSS and HbSβ^0-thalassemia suggest that retinal vessels are more susceptible to occlusion by more viscous blood than by more rigid individual cells. Peripheral sickle retinopathy may require vision-saving therapy with laser photocoagulation. Orbital compression syndrome caused by vaso-occlusion of the periorbital marrow space and subperiosteal hemorrhage has been observed to result in headache, fever, and palpebral edema. In this situation, culture, CT scan, and MRI should be used to rule out infectious, neoplastic, and other hemorrhagic etiologies. Conservative therapy, including local measures, analgesia, fluids, transfusion, and careful ophthalmologic surveillance, is recommended unless compression of the optic nerve ensues, in which case surgical decompression should be considered.

Bone Complications

Chronic tower skull, bossing of the forehead, and fish-mouth deformity of the vertebrae are the result of extended hematopoietic bone marrow, causing widening of the medullary space, thinning of the trabeculae and cortices, and osteoporosis. Osteonecrosis may cause a steplike depression of the vertebrae, selected shortening of the cuboidal bones of the hands and feet, and acute aseptic or avascular necrosis. The excruciating pain of bone infarction in the "hand–foot syndrome" that occurs around 2 years of age is often the first symptom of SCD (Fig. 43.15).[343] This dactylitis resolves spontaneously and is treated with hydration and analgesia. Bone infarcts are demonstrable using nuclear medicine scintigraphy or MRI. Serial scans specific for bone osteoclasts, bone marrow macrophages, and inflammatory cells may be useful adjuncts for distinguishing bone marrow infarction from osteomyelitis, but it is essential to obtain cultures directly from the affected tissue before starting antibiotics. Treatment of osteomyelitis is addressed in the Infection sections.

Osteonecrosis (avascular necrosis) is a prevalent skeletal complication attributed to repetitive ischemia-reperfusion injury in vulnerable articular surfaces. Recurrent painful VOC episodes result in compromised blood flow to all joints and increase the risk for multifocal osteonecrosis. Bone necrosis occurs with equal frequency in the femoral and humeral heads, but the femoral heads more commonly undergo progressive joint destruction as a result of lack of collateral blood flow and chronic weight bearing. Approximately 50% of adult patients with HbSS disease will develop osteonecrosis of the femoral heads by the age of 35.[344] Risk factors include male gender, high body mass index, leukopenia, concomitant alpha thalassemia trait with higher Hb, frequent VOC, and multiple episodes of ACS.[345] All children and adults with intermittent hip pain should undergo screening with plain films and/or MRI as per 2014 evidence-based NHLBI guidelines. The process is associated with increased intraosseous pressure and is most sensitively detected by MRI. Aggressive physical therapy appears to prevent progression in mild cases and should be considered in the therapy of avascular necrosis. Core decompression surgery to relieve increased intraosseous pressure can be used in early-stage osteonecrosis (i.e., no radiographic evidence of bone collapse) to prevent disease progression. In more advanced disease, joint replacement should be considered. There is a 30% likelihood that a

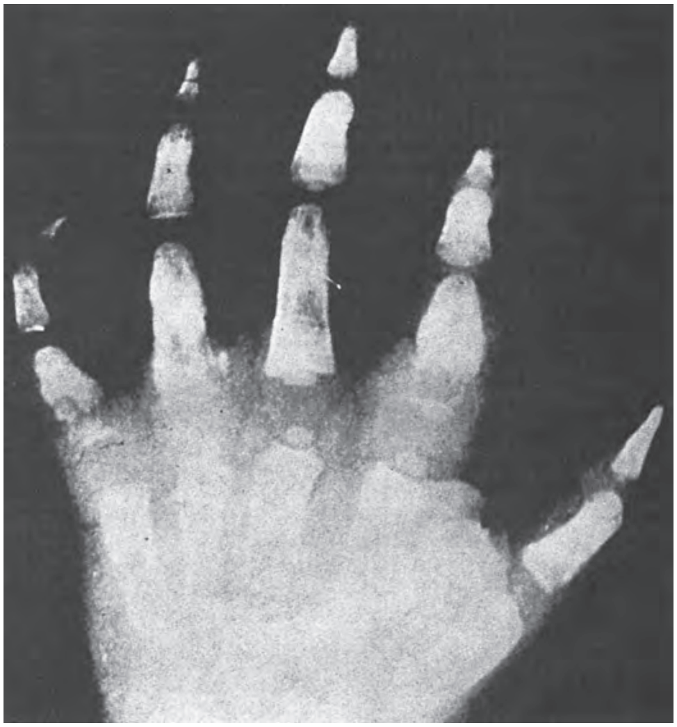

Figure 43.15 RADIOGRAM SHOWING THE BONE INFARCTIONS IN THE HANDS OF A CHILD WITH THE "HAND–FOOT SYNDROME" DACTYLITIS. *(Courtesy W. C. Mentzer.)*

second hip revision will be required within 4 to 5 years of prosthetic hip placement in patients with SCD.[346] However, the outlook for total hip replacement in SCD has greatly improved with cementless ceramic prosthetic devices and joint management by an experienced surgeon and hematologist, prompting earlier intervention.[347,348]

Arthritic pain, swelling, and effusion may be related to periarticular infarction or gouty arthritis.

Bone marrow infarction causes reticulocytopenia, exacerbation of anemia, a leukoerythroblastic picture, and sometimes pancytopenia.[214,215] Pulmonary fat embolism is a rare complication of bone marrow infarction.[349] It is associated with fat globules in the sputum and refractile bodies visible in the optic fundi. It is a life-threatening event that may require prompt exchange transfusion and perhaps the use of heparin and corticosteroids.[349]

Dermatologic Complications

Leg ulcers are major causes of morbidity in SCD as a result of their frequency, chronicity, and resistance to therapy. Most occur near the medial or lateral malleolus (Fig. 43.16), may be associated with venous hypertension[350] and hemolytic rate,[351] and are frequently bilateral.[352] They may begin spontaneously or as a result of trauma and may become infected, most commonly by *S. aureus, Pseudomonas* spp., streptococci, or *Bacteroides* spp. Systemic infection, osteomyelitis, and tetanus are rare complications. Ulcers are resistant to healing and tend to be recurrent in well over half of cases. Their incidence has been reported to vary from 25% to 75%.[353] Ulcers rarely occur in patients younger than age 10 years and are most common in SCA (HbSS and HbSβ^0-thalassemia), and almost nonexistent in HbSC disease and HbSβ^+-thalassemia.[352] The incidence in SCA patients declines substantially in those who have coexistent α-thalassemia.[354] Low steady-state Hb levels and low HbF levels are associated with an increased risk of leg ulceration.[354] Males have a threefold greater risk for developing leg ulcers than females. Treatment of leg ulcers requires persistence and patience; healing usually takes weeks. Therapy[355] begins with gentle debridement to remove nonviable, superficial tissue from more vital areas. Wet-to-dry dressings and DuoDerm hydrocolloid dressings facilitate devitalization. When debridement is complete, zinc oxide–impregnated Unna boots are used to promote healing. Bed rest speeds healing,[356] and topical antibiotics may be required. It may be necessary to use elastic wraps or leg elevation to control edema. Rapid healing of leg ulcers has been reported in patients treated with intravenous arginine butyrate.[357] Oral zinc, local hyperbaric oxygen, chronic transfusion, recombinant EPO, propionyl-L-carnitine, skin grafts, pentoxifylline, and becaplermin (platelet-derived growth factor) may have therapeutic roles and should be considered in individual cases but have not been formally tested for their effectiveness in accelerating resolution of sickle cell–associated leg ulcers.

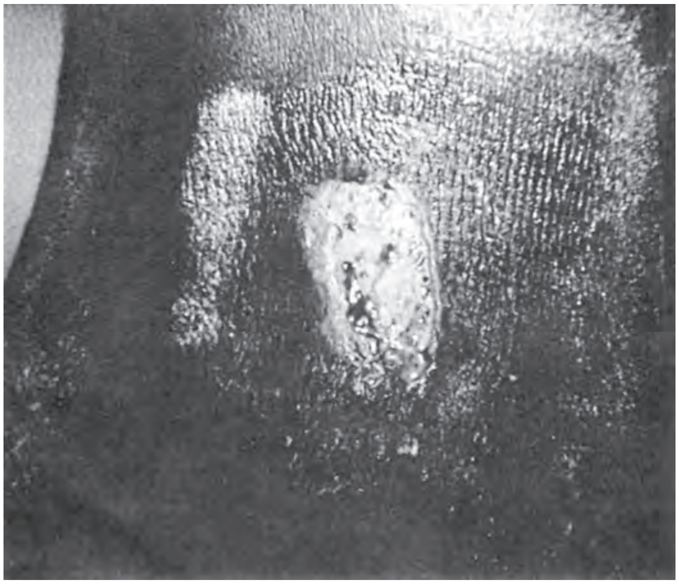

Figure 43.16 CHRONIC LEG ULCER NEAR THE MEDIAL MALLEOLUS. *(Courtesy W. C. Mentzer.)*

Myofascial syndromes consist of soft tissue swelling in subcutaneous edema that may have a *peau d'orange* appearance. These may be large or discrete lesions a few centimeters in diameter. These lesions are probably the result of dermal or subdermal vaso-occlusion. Treatment is symptomatic.

Cardiac Complications

The chronic anemia of SCD is compensated by high cardiac output, which results in chronic chamber enlargement and cardiomegaly, and mild to moderate mitral and tricuspid regurgitation even in young children. The electrocardiogram shows evidence of left ventricular hypertrophy and less often first-degree block and nonspecific ST-T wave changes. Left ventricular dilation correlates with age and inversely correlates with total Hb.[358] An age-dependent loss of cardiac reserve may predispose to heart failure in adult patients stressed by fluid overload, transfusion, exacerbation of anemia, hypoxia, or hypertension.[359] Cardiac function can be improved by chronic transfusion regimens.[360] Acute myocardial infarction in the absence of coronary disease has been reported, and in one autopsy series, 9.7% of 72 consecutive patients with SCD had myocardial infarction.[361] It appears that myocardial infarction may occur with normal coronary arteries as a result of increased oxygen demand exceeding limited oxygen-carrying capacity or as a result of microcirculatory impairment. As discussed earlier, PH is a relatively common finding in patients with SCD and can be associated with right ventricular hypertrophy. It has been suggested that the increased rate of sudden death observed in SCD may be related to cardiac autonomic dysfunction, as detected by abnormal heart rate variability in response to selected postural maneuvers.[362]

Multiorgan Failure

This disastrous acute event involves multiple organ systems, including the lungs, brain, kidneys, liver, hematologic system, and heart, and usually leads to death.[363] It may be precipitated by infection, vaso-occlusion, or fat embolus and consists of a constellation of life-threatening processes, including hypoxemia, acidosis, inflammation, vascular permeability, severe anemia, disseminated intravascular coagulation, renal failure, and hepatic failure. In addition to therapy specific for these processes, exchange transfusion, plasma infusion or exchange, and corticosteroids should be considered.

Psychosocial Issues

Modern insights into the psychosocial adjustment of patients with SCD have provided a level of understanding that allows interventional therapy. Although most patients with SCD are generally well adjusted,[364] there are risks of depression, low self-esteem, social isolation, poor family relationships, and withdrawal from normal daily living.[364] Particular stressors are recurrent and unpredictable pain and the response to it, curtailed activity because of pain, misinterpretation of the meaning of pain, and depression leading to learned helplessness. Although some patients with SCD become addicted to narcotics, this is uncommon and usually is the result of social influences rather than pain therapy. Active coping strategies, family support, and support from the extended family unit are paramount. Interventional approaches should emphasize recognizing and reinforcing individual strengths; confronting pathologic behavior; and establishing coping skills through reinterpreting pain, diverting attention from pain, and using support systems.[365] Attention to psychosocial concerns is vital to the psychosocial well-being of patients with SCD (see Chapter 98).

Growth and Development

By age 2 years, children with SCD have detectable growth retardation that affects weight more than height and has no clear gender difference.[366] By adulthood, normal height is achieved, but weight remains lower than that of control participants. More severe growth delay is noted in children with HbSS and HbSβ^0-thalassemia; HbSC disease is associated with a less severe growth delay. Girls with SCD have retarded sexual maturation that is greater in those with HbSS and HbSβ^0-thalassemia than those with HbSC disease and HbSβ^+-thalassemia[366]; it is associated with elevated gonadotropin levels for the stage of sexual development and delayed menarche. Boys also have delayed sexual maturation, which is more severe in those with HbSS than those with HbSC disease.[366] Retarded sexual maturation in boys can be attributable to primary hypogonadism, hypopituitarism, or hypothalamic insufficiency. The etiology of these multiple endocrine deficiencies may relate to underlying sickle cell pathophysiology or iron overload and emphasizes the importance of a comprehensive basic management and disease modification approach as outlined earlier in this chapter. Improved growth has been reported with HU,[367] transfusion,[367] folic acid supplementation, zinc supplementation,[368] and nutritional supplementation.[369] When children have both SCD and hypersplenism, splenectomy may result in improved protein turnover, metabolic rate, and growth parameters.[370] Although most SCD patients worldwide have low BMI, in the better-resourced countries obesity is increasing among SCD patients, and was noted to be as high as 50% in a small US cohort.[371] Obesity is correlated with hypertension, sleep apnea, and cardiovascular complications in SCD patients and has been proposed as the "sixth vital sign."[372]

Sickle Cell Trait

The prevalence of sickle cell trait is approximately 8% to 10% in African Americans and as high as 25% to 30% in certain areas of western Africa.[16] An estimated 2.5 million people in the United States and 300 million in the world (~5% of the world's population) are heterozygous for the sickle cell gene.[373] Sickle cell trait is largely a benign carrier condition without obvious laboratory hematologic manifestations under basal conditions: RBC morphology, RBC indices, and the reticulocyte count are normal, and ISCs are not seen on the peripheral blood smear. The usual partition of HbA and HbS in sickle cell trait is 60:40 owing to a greater posttranslational affinity of α chains for β^A than for β^S chains.[23] When α-thalassemia is coinherited with sickle cell trait, the preferential affinity results in a decreased percentage of HbS relative to the number of α-globin genes deleted (i.e., $\alpha\alpha/\alpha\alpha$ 40% HbS; $-\alpha/\alpha\alpha$ 35% HbS; $-\alpha/-\alpha$ 29% HbS; $--/-\alpha$ 21% HbS).[210]

Life expectancy is not reduced by heterozygosity for the sickle cell mutation.[374] There are several clinical complications associated with sickle cell trait. Splenic infarction can occur at high altitudes[375] and presenting symptoms may include left upper quadrant pain and elevated bilirubin levels. Therapy is primarily supportive including changing altitude although splenectomy may be required in a small percentage of cases. Rare cases of splenic sequestration reported in the literature have been triggered by dehydration, rigorous physical exercise, high altitudes, or increased pressure associated with scuba diving. People with sickle cell trait also may develop hematuria and hyposthenuria which are generally attributed to renal papillary infarcts.[376] There is preliminary evidence suggesting that individuals with sickle cell trait are at greater risk for developing proteinuria and CKD, but further research is required to clarify these findings.[377] The frequency of urinary tract infection may be increased. There is an association with RMC and individuals with unexplained hematuria should undergo prompt evaluation with CT imaging.[334] There is an increased risk for venous thrombosis with an approximately twofold increase in risk and sickle trait explaining 7% of thrombotic episodes in African Americans.[377] Armed forces recruits in basic training with the sickle cell trait have a substantially increased, age-dependent risk of exercise-related sudden death.[327]

Despite the known complications, past experiences with discrimination in the employment market and health insurance industry provide reminders that the rare clinical events in sickle cell trait provide no real justification for regarding it as anything but a benign carrier condition.[317] Newborn screening programs detect a large number of infants with sickle cell trait; for these parents, genetic counseling is essential. Parents should understand that their child has a hereditary condition with some risks as above and that there is a risk for subsequent offspring to be born with SCD.

In individuals who appear to have sickle cell trait but are symptomatic, the laboratory diagnosis must be verified, and detailed family history is very important.[317] Heterozygotes for double mutants, HbS Antilles[378] and Hb Jamaica Plain[379] can present with symptoms of moderate to severe SCD. Compound heterozygotes of HbS with Hb Arlington Park and HbS with Hb Quebec-CHORI produce a severe sickling phenotype. In both cases, since the variant Hbs migrate like HbA on electrophoresis, compound heterozygosity with HbS can be mistaken for sickle cell trait on electrophoresis. In other cases, co-inheritance of non-hemoglobin red cell disorders (e.g., Red cell membrane and enzyme) can have important modifying effects on the clinical outcome of sickle cell carriers. An example is the concomitant inheritance of pyruvate kinase deficiency, which lowers hemoglobin oxygen affinity due to an accumulation of the upstream glycolytic intermediate, 2,3-DPG, thus increasing HbS polymerization.[380,381]

HbSC Disease

The gene for HbC ($\alpha_2\beta_2{}^6$Glu→Lys) is approximately one-fourth as frequent among African Americans as the sickle cell gene.[16] Hemoglobin analysis demonstrates approximately equal amounts of HbS and HbC (or slightly more HbS than HbC) and no HbA is present. Although oxygenated HbC forms crystals, HbC does not participate in polymerization with deoxy-HbS. However, HbC sustains potassium chloride cotransport and RBC dehydration, raising the intraerythrocytic concentration of HbS to levels that support polymerization, sickling, and clinical symptoms. As a result of a longer circulatory survival of HbSC RBCs compared with HbSS cells (i.e., 27 vs. 17 days),[208] the degree of anemia and reticulocytosis is frequently mild: 75% of the patients have a milder level of anemia (hematocrit level >28%) than is usually seen in SCA. The predominant RBC abnormality on the peripheral smear is an abundance of target cells; folded ("pita bread") cells, ISCs, "billiard ball" cells, and crystal-containing cells may also be seen.

Splenomegaly may be the only physical finding, and the frequency of acute painful episodes is approximately half that in HbSS disease, with a life expectancy two decades longer.[40] HU therapy may be beneficial in selected patients with frequent VOC episodes and appears safe. Patients are at risk for hyperviscosity syndrome secondary to increased Hb levels, and may benefit from therapeutic phlebotomy.[382] Nonetheless, significant morbidity can occur. The incidence of fatal bacterial infection is less than in SCA, but there is still an increased risk of *S. pneumoniae* and *H. influenzae* infection. Osteonecrosis occurs in approximately 15% of patients.[383] There is a higher incidence of peripheral retinopathy in HbSC disease, in some cohorts as high as 70%,[383] than in SCA. Coexistent α-thalassemia reduces risk of chronic organ complications.[384] There is an association between RMC and HbSC disease.

Sickle Cell–β-Thalassemia

Beta-thalassemia results in impaired production or absence of beta-globin chains. In compound heterozygotes of HbS with β-thalassemia, HbS comprises the majority of the total hemoglobin with some (HbS/β^+-thalassemia), or no HbA (HbSβ^0-thalassemia), and the outcome is dependent of the severity of the beta-thalassemia mutation. The gene frequency of β-thalassemia among African Americans is 0.004, one-tenth that of the sickle cell gene,[16] and hence there is one-tenth the prevalence of compound heterozygous sickle cell–β-thalassemia in this population. Individuals of Hispanic ethnicity are also at risk for sickle beta-thalassemia. HbS–β-thalassemia is divided into HbSβ^+-thalassemia and HbSβ^0-thalassemia, which have, respectively, reduced or no amounts of Hb A present. Most β-thalassemia mutations among African Americans result in mild β^+-thalassemia; 80% of African American β-thalassemia mutations are attributable to the promoter region mutations (−88 [C to T] and −29[A to G]) that result in a minor deficit of HbA production, ranging from 18% to 25%. Compound heterozygous HbSβ^0-thalassemia occurs infrequently.

In HbSβ-thalassemia, the RBCs are hypochromic and microcytic; HbA2 is higher than normal (3.5% to 4.2%) in SCD and thus is not a good diagnostic guide. The ISCs present on the peripheral blood smear are more numerous in HbSβ^0-thalassemia than in HbSβ^+-thalassemia. The hematologic and clinical severity is a function of the amount of HbA inherited (Table 43.10), thus the majority of HbSβ^+-thalassemia in African Americans tend to be mild unlike those of Mediterranean descent where β^+-thalassemia mutations result in a severe deficit of HbA production.[387,390] Additional mitigating influences in HbSβ-thalassemia are elevated levels of Hb A_2.

In HbSβ^+-thalassemia, levels of Hb A range up to 30%. These affect both the solubility and polymerization of HbS. HbF is a more active inhibitor of polymerization than HbA, as shown by HbS solutions with 15% to 30% Hb A (HbSβ^+-thalassemia) having delay times 10 to 100 times longer than pure HbS solutions, and HbS solutions with 20% to 30% HbF (resembling HbS/HPFH) having delay times 1000 to 1,000,000 times longer. A further influence mitigating the polymerization, sickling, and clinical aspects of HbSβ-thalassemia is the reduced MCHC, which retards HbS polymerization. Hematologic values for SCA, the HbSβ-thalassemias, and HbS/HPFH are found in Table 43.10.

For patients with sickle cell β^0-thalassemia who do not have any HbA, the clinical outcome is similar to that of HbSS disease with similar incidence of acute pain crises and ACS.[57,386] In addition, rates of PH appear similar between sickle cell–β^0-thalassemia and HbSS disease cohorts. Sickle cell β^0-thalassemia patients develop functional asplenia during infancy and have an increased rate of sepsis, including pneumococcal sepsis as for HbSS patients.

In general, sickle cell β^+-thalassemia is associated with a more mild disease phenotype, with a later age of presentation and less frequent pain crises and episodes of ACS. There is a higher incidence of proliferative retinopathy given that higher Hb levels and blood viscosity are associated with ocular complications However, the genotype-phenotype correlations in sickle cell β^+-thalassemia are variable; a key factor here is the type and severity of β^+-thalassemia mutations.

Sickle Cell–Hemoglobin Lepore Disease

The Hb Lepore gene is a crossover fusion product of the δ- and β-globin genes, the product of which, in the case of Hb Lepore Boston, has the same alkaline electrophoretic mobility as HbS. Therefore patients with the Hb Lepore trait can appear to have sickle cell trait but with only 12% HbS from thalassemic expression of the abnormal fusion gene. Again, because of the electrophoretic similarity with HbS, compound heterozygous HbSHb Lepore Boston resembles SCA or sickle cell–β^0-thalassemia electrophoretically but clinically has less severe anemia, resembling that of sickle cell–β^+-thalassemia. The diagnosis is also suggested by the low to low-normal Hb A_2 levels that result from the incapacitation of one δ-globin gene by the crossover. HbF levels vary. The peripheral smear shows microcytosis, hypochromia, and ISCs. Vaso-occlusive complications occur, and splenomegaly is common.

TABLE 43.10 **Hematologic Variables Associated With Sickle Cell Anemia and the Different Sickle Cell–β-Thalassemia Syndromes**

Genotype	Hb[a]	%HbA[b]	%HbF[b]	%HbA2[a]	MCV[a]	Reticulocytes[a]	*n*
HbSS[c]	7.83	0	4.56	2.87	85.9	10.18	≈123
HbSβ^0-thalassemia[c]	8.85	0	5.86	5.02	69.3	7.2	≈41
HbSβ^+-thalassemia, type I[d]	8.37	3-5	6.8	4.90	63.7	9.7	3
HbSβ^+-thalassemia, type II[d]	10.28	8-14	5.2	4.68	70.0	6.6	14
HbSβ^+-thalassemia, type III[e]	11.55	18-25	5.1	4.66	73.3	1.27	76
HbS/HPFH[f]	14.6	0	25.8	1.95	81.7	2.4	4

[a] The mean data for each variable are shown. Units of measure are grams per deciliter for Hb, percentage of total hemoglobin for HbF and A2, fl for MCV, and percentage of total red blood cells for reticulocytes.

[b] Percentage HbA that defines the HbS–β^+-thalassemia type.[385]

[c] Data from Serjeant et al.[386]

[e] Data from Serjeant et al.[390]

[f] Data from Friedman et al.[389]

Hb, Hemoglobin; *HPFH*, persistence of fetal hemoglobin; *MCV*, mean corpuscular volume

Sickle Cell–Hemoglobin D Disease[384]

Because HbD Punjab or HbD Los Angeles ($\alpha_2\beta_2{}^{127}$Glu→Gln) has a similar electrophoretic mobility to HbS under alkali conditions. HbSD disease was first reported as an unusual case of SCA. HbD can be distinguished from HbS by acid electrophoresis or isoelectric focusing. There is moderately severe hemolytic anemia, and the peripheral smear shows marked anisocytosis and poikilocytosis, target cells, and ISCs. The clinical manifestations of this syndrome are similar to those of SCA.

Sickle Cell–Hemoglobin O Arab Disease[385]

Although HbO Arab ($\alpha_2\beta_2{}^{127}$Glu→Lys) was first described in an Israeli Arab family, its distribution is widespread. Sickle cell–O Arab disease resembles HbSC disease on alkaline electrophoresis, but HbO Arab can be distinguished from HbC by acid electrophoresis or isoelectric focusing. This syndrome is associated with moderately severe hemolytic anemia, and the peripheral smear shows anisocytosis, poikilocytosis, and ISCs. Oxygen affinity is reduced in sickle cell-HbO Arab as compared to SCD. Clinical manifestations are severe and resemble that of homozygous HbSS disease.[385]

Sickle Cell–Hemoglobin E Disease[1]

HbE ($\alpha_2\beta_2{}^{26}$Glu→Lys) is a β-thalassemic hemoglobinopathy found predominantly in Southeast Asia (see Chapter 41). The structural mutant has an electrophoretic mobility similar to HbC under alkaline conditions but can be resolved by acid electrophoresis or isoelectric focusing. The GAG→AAG mutation in codon 26 activates a cryptic splice site within the first intron of the β^E gene, causing alternate splicing and decreased expression of the structural mutant, resulting in a mild beta thalassemia phenotype. As a result, HbE makes up only 30% of the total Hb in compound heterozygosity for the sickle cell and HbE genes. HbSE disease is essentially benign in at least 50% and possibly most patients, with only mild hemolysis, no vaso-occlusive complications, and no remarkable abnormality of RBC morphology. However, vaso-occlusive complications and manifestations of chronic hemolytic anemia such as pain crisis, splenic infarction, recurrent pneumonia, and frontal bossing have been reported.

Coinherited Hemoglobin Abnormalities That Interact With Sickle Cell Disease: Hereditary Persistence of Fetal Hemoglobin and α-Thalassemia Trait

Sickle Cell–Hereditary Persistence of Fetal Hemoglobin

Adult Hb (or in the case of SCA, HbS) replaces HbF as a result of the switch from γ- to β-globin synthesis that occurs in fetuses. Because of the inhibitory effect of HbF on HbS polymerization and cellular sickling (see Chapter 42), the high fraction of HbF at birth masks the expression of SCD until HbS levels increase to 75% at approximately 6 months of age (see Fig. 43.3). Conditions that preserve elevated levels of HbF into adulthood similarly modulate the course of SCD, and this persistence of HbF production into adulthood is referred to as HPFH.[389] Common forms of variable HPFH are associated with co-inheritance of genetic variants on the β^S-haplotype, *BCL11A* gene, and the *HBS1L-MYB* intergenic region on chromosome 6q. The level of HbF in HbSS and HbSβ^0-thalassemia depends on the number of HbF boosting alleles inherited,[388] in some case the HbF can be as high as 25% to 30% but the distribution of HbF among the red cells is not uniform, i.e. heterocellular. Rarely, individuals are compound heterozygotes for HbS and HPFH caused by deletions of the beta-globin gene cluster or point mutation changes in the promoter of the gamma-globin genes. The most common form of gene deletion HPFH is the Ghanaian HPFH. In HbS/HPFH, the HbF is 30% to 40% and the rest is HbS, the concentration of HbF is homogeneous in every red cell, and individuals with HbS/HPFH have minimal or no sickle-related complications. It is likely that many cases of apparent SCA with unexplained elevations of HbF are the result of a heterocellular HPFH related to co-inheritance of genetic variants boosting HbF production on a background of stress erythropoiesis.

The gene frequency of the deletional HPFH locus is 0.0005 among African Americans, resulting in a calculated incidence for compound heterozygous sickle cell–deletional HPFH of 1/100 that of SCA. HbS/deletional HPFH provided the first evidence that HbF was a potent inhibitor of HbS polymerization: individuals with pancellular distribution of 25% HbF were generally neither anemic nor affected with vaso-occlusive manifestations (see Table 43.10).[389] Hb electrophoresis revealed only HbS, F, and A_2, which resembles HbSS, HbSβ°-thalassemia, and HbSδβ^0-thalassemia. Notable differences, however, are the pancellular distribution of 15% to 35% HbF, HbA_2 levels less than 2.5%, and the absence of anemia.[391,392] The generally benign course of HbS/deletional HPFH is uncommonly associated with vaso-occlusive complication.

Sickle Cell Anemia with Coexistent α-Thalassemia

Prevalences of the silent carrier of α-thalassemia syndrome (genotype −α/αα) and α-thalassemia trait (genotype −α/−α) among African Americans are approximately 30% and 2%, respectively.[393] The peripheral blood smear contains less polychromasia and fewer sickle forms and more hypochromia and microcytosis, commensurate with the numbers of α-globin genes deleted. Increased Hb A_2 levels are associated with increasing α-globin gene deletions; the HbF levels are not consistently affected.

Clinically, the impact of α-globin gene deletions on sickle cell is not as consistent as that of high HbF.[45,149] Because of the powerful effect of HbS concentration on the kinetics and extent of HbS polymerization (see Chapter 42), the lower MCHC from α-globin gene deletions decreases the hemolytic rate, and anemia is milder in subjects with both α-thalassemia syndrome (genotype −α/αα) and trait (genotype −α/−α) (see Table 43.1). In one series, hemoglobin concentration was 9.8 g/dL in patients with SCD and the (-a/aa) genotype compared with 7.9 g/dL in those with HbSS disease.[45] There is a decreased incidence of leg ulcers but an increased incidence of osteonecrosis. The frequency of retinal vessel closure is higher but not the incidence of retinopathy. Complications related to hemolysis (e.g., leg ulcers, chronic renal damage) may be decreased, but the heterogeneity of the patients in previous studies and mixed results make conclusions difficult. Similarly, the influence of α-gene deletions on survival in patients with SCD is not well understood.[50]

CHAPTER 44

HEMOGLOBIN VARIANTS ASSOCIATED WITH HEMOLYTIC ANEMIA, ALTERED OXYGEN AFFINITY, AND METHEMOGLOBINEMIAS

Edward J. Benz, Jr. and Benjamin L. Ebert

Hemoglobinopathies are inherited diseases caused primarily by mutations affecting the globin genes. Nearly 1000 mutations are known to alter the structure, expression, or developmental regulation of individual globin genes and the hemoglobins that they encode. Of these, only a few produce clinical disease. Many are highly instructive for students of gene structure, function, and regulation, but further consideration of most is not warranted in a clinically oriented textbook. The gene mutations that cause sickle cell anemia and the thalassemia syndromes are by far the most important mutations that cause clinical morbidity, in terms of both the complexity of the clinical syndromes they cause and the number of patients affected. These conditions are considered in detail in other chapters (see Chapters 41, 42, and 43). This chapter reviews additional abnormalities of the hemoglobin molecule that produce clinical syndromes. Even though each variant is uncommon, these hemoglobinopathies represent, in the aggregate, important problems for hematologists because they must be considered as possible causes for conditions about which hematologists are often consulted: hemolytic anemia, cyanosis, polycythemia, jaundice, premature gallstones, rubor, hepatosplenomegaly, and reticulocytosis. In some patients, secondary hematologic complications such as hypercoagulable states are also encountered.

The major inherited hemoglobinopathies producing clinical symptoms (other than sickle cell anemia and thalassemias) can be classified as those hemoglobins exhibiting altered solubility (unstable hemoglobins), hemoglobins with increased oxygen affinity, hemoglobins with decreased oxygen affinity, and methemoglobins (Table 44.1). A few acquired conditions in which toxic modifications of the hemoglobin molecule are important (e.g., acquired methemoglobinemia and carbon monoxide poisoning) also merit consideration.

The sections that follow emphasize hemoglobinopathies that produce the most severe or dramatic alterations in clinical phenotype and those in which a single clinical abnormality (e.g., hemoglobin precipitation) predominates. However, it is important to emphasize at the outset that, although more than 100 mutations affect solubility or affinity, only a few are clinically important. The abnormal functional properties of most mutant hemoglobins can be readily detected in sophisticated research laboratories, but only a few mutant hemoglobins produce laboratory or clinical abnormalities relevant to clinical practice. Moreover, many mutations are pleiotropic, affecting several functional properties of the hemoglobin molecule. Thus a single mutation can increase oxygen affinity and reduce solubility or produce methemoglobinemia and reduce solubility.

Table 44.2 summarizes the major forms of structurally abnormal hemoglobin, with examples. This table serves as a point of reference for the remaining sections of the chapter.

UNSTABLE HEMOGLOBINS

Unstable hemoglobins are hemoglobins exhibiting reduced solubility or higher susceptibility to oxidation of amino acid residues within the individual globin chains. More than 100 unique unstable hemoglobin mutants have been documented. Most exhibit only mild instability in in vitro laboratory tests and are associated with minimal clinical manifestations. Both α- and β-globin variants can cause this condition. However, approximately 75% of the mutations described are β-globin variants. This probably reflects the potential for α-globin variants to exert pathologic effects in utero. Clinical symptoms of unstable hemoglobins also depend, in part, on the quantitative proportion of the abnormal hemoglobin. Because the α-globin genes are duplicated, mutations in an individual locus generally produce only 25% to 35% abnormal globin. By contrast, a simple heterozygote at the single β-globin locus usually produces approximately 50% of the abnormal variant.

The mutations that impair hemoglobin solubility usually disrupt hydrogen bonding or the hydrophobic interactions that either retain the heme moiety within the heme-binding pockets or hold the tetramer together (Fig. 44.1). Some alter the helical segments (e.g., hemoglobin [Hb] Geneva [$\beta^{28\text{Leu}\rightarrow\text{Pro}}$]), others weaken contact points between the α and β subunits (e.g., Hb Philadelphia [$\beta^{35\text{Tyr}\rightarrow\text{Phe}}$]), and still others derange interactions of the hydrophobic pockets of the globin subunits with heme (e.g., Hb Köln [$\beta^{98\text{Val}\rightarrow\text{Met}}$]). The common pathway to reduced solubility invariably involves weakening of the binding of heme to globin. Actual loss of heme groups can occur; for example, in Hb Gun Hill, five amino acids, including the F8 histidine that is crucial for heme binding, are deleted. In other cases, mutations that introduce prolines into helical segments disrupt the helices and interfere with normal folding of the polypeptide around the heme group. Another feature of these mutations is disruption of the integrity of the tetrameric structure of globin chains. Only the intact hemoglobin tetramer can remain dissolved at the high concentrations that must be achieved within the circulating red blood cell (see Chapters 34 and 41).

Pathophysiology of Unstable Hemoglobin Disorders

The mechanisms by which unstable hemoglobin mutations produce hemoglobin precipitation remain incompletely understood; however, the major outlines of the process have been described (Fig. 44.2). The fundamental step in pathogenesis appears to be derangement of the normal linkages between heme and globin. Loss of appropriate globin chain folding and interaction ultimately destabilizes the heme–globin linkage and likely leads to partial proteolysis of the chain, thereby releasing heme from that linkage. Once freed from its cleft, heme probably binds nonspecifically to other regions of the globin molecule, forming precipitated hemichromes, these lead to further denaturation and aggregation of the globin subunits. These form a precipitate containing α- and β-globin chains, globin fragments, and heme, called the *Heinz body*.

Heinz bodies interact with delicate red blood cell membrane components (see Chapter 46), thereby reducing red blood cell deformability. These rigid cells tend to be detained in the splenic microcirculation and “pitted,” reflecting attempts by the splenic macrophages to remove the Heinz bodies. Red blood cell damage can be

TABLE 44.1 Classification of Hemoglobinopathies

Structural hemoglobinopathies: hemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties

Abnormal Hemoglobin Polymerization: HbS

Altered Oxygen Affinity

High affinity: polycythemia
Low affinity: cyanosis, pseudoanemia

Hemoglobins That Oxidize Readily

Unstable hemoglobins, hemolytic anemia, jaundice
M hemoglobins: methemoglobinemia, cyanosis

Thalassemias: Defective Production of Globin Chains

α-Thalassemias
β-Thalassemias
δβ-, γδβ-, αβ-Thalassemias
Structural hemoglobinopathies: structurally abnormal Hb associated with coinherited thalassemia phenotype
HbE
Hb Constant Spring
Hb Lepore

Hereditary Persistence of Fetal Hemoglobin: Persistence of High Levels of HbF Into Adult Life

Pancellular: all red blood cells contain elevated HbF levels
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellular: only specific subpopulation of red blood cells contains elevated levels of HbF

"Acquired Hemoglobinopathies"

Methemoglobin due to toxic exposures
Sulfhemoglobin due to toxic exposures
Carboxyhemoglobin
HbH in erythroleukemia
Elevated HbF in states of erythroid stress and bone marrow dysplasia, usually heterocellular

Hb, Hemoglobin.

TABLE 44.2 Mutations Producing Abnormal Hemoglobin Molecules[a]

Residue	Mutation	Common Name(s)	Molecular Pathology
Abnormal Solubility			
β6	Glu→Val	S	Polymerization
β6	Glu→Lys	C	Crystallization
β121	Glu→Gln	D-Los Angeles, D-Punjab	Increases polymer in S/D heterozygote
β121	Glu→Lys	O-Arab	Increases polymer in S/O heterozygote
Increased Oxygen Affinity			
α92	Arg→Gln	J-Capetown	Stabilizes R state
α141	Arg→His	Suresnes	Eliminates bond to Asn 126 in T state
β89	Ser→Asn	Creteil	Weakens bonds in T state
β99	Asp→Asn	Kempsey	Breaks T state intersubunit bonds
Decreased Oxygen Affinity			
α94	Asp→Asn	Titusville	Alters R state intersubunit bonds
β102	Asn→Thr	Kansas	Breaks R state intersubunit bonds
β102	Asn→Ser	Beth Israel	Breaks R state intersubunit bonds
Methemoglobin			
α58	His→Tyr	M-Boston, M-Osaka	Heme liganded to Tyr not His
α87	His→Tyr	M-Iwate	Heme liganded to both His and Tyr
β28	Leu→Gln	St Louis	Opens heme pocket
β63	His→Tyr	M-Saskatoon	Tyr ligand stabilizes ferriheme
β67	Val→Glu	M-Milwaukee-I	Negative charge stabilizes ferriheme
β92	His→Tyr	M-Hyde Park	Bond of His to heme disrupted
Unstable			
α43	Phe→Val	Torino	Loss of heme contact
v94	Asp→Tyr	Setif	Alters subunit contacts
β28	Leu→Gln	St Louis	Polar group in heme pocket
β35	Tyr→Phe	Philadelphia	Loss of dimer bond favors precipitation
β42	Phe→Ser	Hammersmith	Loss of heme
β63	His→Arg	Zurich	Opens heme pocket
β88	Leu→Pro	Santa Ana	Disrupts helix
β91	Leu→Pro	Sabine	Disrupts helix
β91-95	Deletion	Gun Hill	Shortens F helix
β98	Val→Met	Köln	Alters heme contact

[a]Partial list includes some of the most widely studied hemoglobin structural mutations.

aggravated by the release of free heme into the red blood cell. Several biochemical perturbations correlate with the presence of free heme, such as generation of reactive oxidants (i.e., hydrogen peroxide, superoxide, and hydroxyl radicals). The end result of this process is premature destruction of the red blood cell, producing hemolytic anemia.

Individual unstable hemoglobins vary in their propensity to generate Heinz bodies and hemolysis. For example, Hb Zurich exhibits relatively mild insolubility. Hemolysis is minimal in nonstressed patients with this variant and becomes clinically apparent only in the presence of additional oxidant stresses, such as infection, fever, or the ingestion of oxidant agents. Because of the propensity of unstable hemoglobins to be hypersensitive to oxidation, some patients with unstable hemoglobins can exhibit episodic appearance or aggravation hemolysis in response to many of the same oxidative stressors as those exacerbating the clinical phenotype of glucose-6-phosphate dehydrogenase (G6PD)-deficient patients (see Chapters 45 and 48).

Patterns of Inheritance and Clinical Manifestations

Unstable hemoglobins are usually inherited as autosomal dominant disorders. However, the rate of spontaneous mutation appears to be high, so the absence of affected parents or siblings does not rule

Figure 44.1 HEMOGLOBIN TETRAMER SHOWING THE POSITION OF THE MORE COMMON, CLINICALLY SIGNIFICANT HEMOGLOBIN MUTANTS. Most of those that have been described occur on the β-chain at invariant residue sites, near critical intermolecular contacts, or in proximity to the prosthetic heme-binding site. *(Modified from Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA: Benjamin-Cummings; 1983. Copyright Irving Geis.)*

out the presence of an unstable hemoglobin in an individual family. Nonetheless, the presence of a positive family history can be a useful adjunct to diagnosis and should provoke consideration of an unstable hemoglobin as the cause of the familial hemolytic diathesis.

The clinical syndrome associated with unstable hemoglobin disorders is often called *congenital Heinz body hemolytic anemia*. This term derives from the fact that only the most severe cases were detected before the widespread availability of sophisticated methods for detecting and characterizing abnormal hemoglobins. Clinical manifestations are highly variable, ranging from a virtually asymptomatic state in the absence of environmental stressors to severe hemolytic anemia manifesting at birth. Patients with chronic hemolysis present with variable degrees of typical symptoms, including anemia, reticulocytosis, hepatosplenomegaly, jaundice, leg ulcers, and a propensity toward premature biliary tract disease.

For Hb variants with a given degree of reduced solubility, the degree of anemia may fluctuate because some of these variants also exhibit altered oxygen affinity. Thus Hb Köln has increased oxygen affinity, resulting in relatively higher levels of tissue hypoxia and erythropoietin stimulation at any given level of hematocrit (see Diagnosis); therefore patients with Hb Köln tend to have higher hematocrit levels than expected on the basis of hemolytic severity because of increased erythropoietin stimulation. By contrast, Hb Hammersmith exhibits decreased oxygen affinity, improving oxygen delivery and allowing patients to function at a lower hematocrit level (see low affinity variants later in this chapter). Hb Zurich possesses, for complex molecular reasons, a higher-than-normal affinity for carbon monoxide. A high carbon monoxy–Hb level develops in patients with Hb Zurich who also smoke. Binding of carbon monoxide protects Hb Zurich from denaturation, thus reducing hemolysis, so these people tend to exhibit lesser degrees of hemolytic anemia than do nonsmoking relatives.

Diagnosis

The presence of an unstable hemoglobin should be suspected in patients with one or more stigmata of accelerated red blood cell

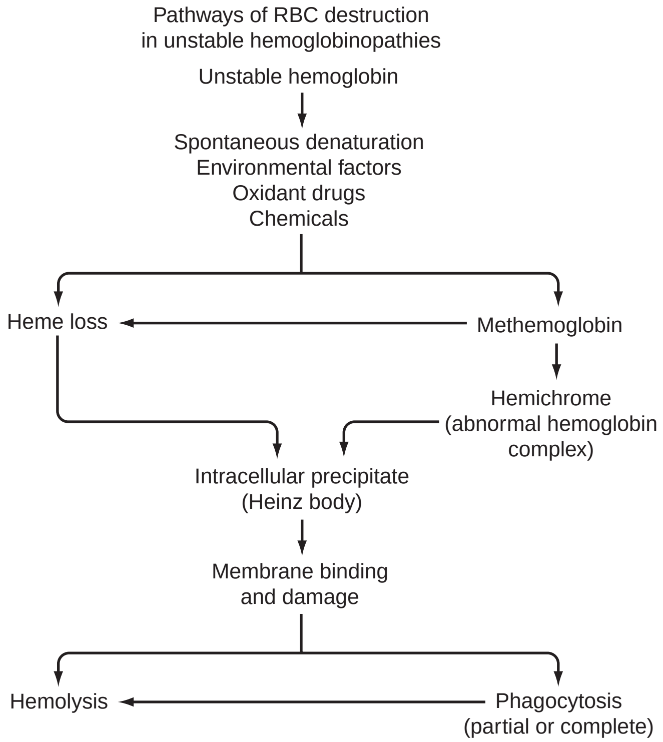

Figure 44.2 PRESUMED MECHANISMS BY WHICH DENATURATION OF HEMOGLOBIN LEADS TO ERYTHROCYTE DESTRUCTION. The rate of travel through the various pathways probably differs for the different hemoglobin variants and for a variety of stresses to which the protein is subjected. *RBC*, Red blood cell. *(From Wynngaarden JB, Smith LH Jr, Bennett JC, eds. Cecil Textbook of Medicine. Philadelphia: WB Saunders; 1992.)*

destruction: chronic or intermittent hemolytic anemia or jaundice, premature development of bilirubin gallstones or biliary tract disease (as a result of accelerated red blood cell turnover), unexplained reticulocytosis, or bouts of intermittent symptoms that can be related to exposure to oxidant drugs or infections. Other suggestive symptoms include dark urine, transient jaundice, and leg ulcers. It is important to remember that significant anemia may or may not be present despite hemolysis brisk enough to produce the other signs and symptoms of accelerated red cell destruction, because of compensatory erythroid hyperplasia, especially in younger otherwise healthy patients.

Laboratory diagnosis depends on identification of a mutant hemoglobin that precipitates more easily than normal hemoglobin. The peripheral blood smear may or may not show evidence of hemolysis (i.e., poikilocytosis, polychromasia, or shift cells; Fig. 44.3A). The morphologic evidence for precipitated hemoglobin is the Heinz body, the intraerythrocytic inclusion body detected by staining the peripheral blood smear with a supravital dye, such as brilliant cresyl blue or new methylene blue (see Fig. 44.3B and C). The spleen removes Heinz bodies efficiently, especially if hemolysis is not particularly acute or brisk. Thus Heinz bodies may not be demonstrable at all times. Two provocative laboratory maneuvers are used to aid detection, both of which unmask the tendency of unstable hemoglobins to precipitate: the heat instability test (heating of a hemoglobin solution to 50°C) or the isopropanol instability test (insolubility in 17% isopropanol).

Hemoglobin electrophoresis should be performed but *should not be relied on as the major diagnostic criterion for ruling in or ruling out a hemoglobinopathy*. Many amino acid substitutions that have a profound effect on solubility do not change the overall charge on the hemoglobin molecule. For example, Hb Köln, the most common of the unstable hemoglobin mutations, arises from a mutation changing the valine at position 98 to a methionine. This mutation is electrically neutral; it does not alter electrophoretic mobility. Therefore these variants do not form an abnormal band on an electrophoresis gel. Demonstration of an abnormal band would clearly add strong evidence in support of the diagnosis. However, a normal electrophoretogram should never be regarded as strong evidence against the presence of a mutant hemoglobin, especially if the clinical picture or family history otherwise supports the diagnosis. Mass spectrometry analysis of hemoglobin and direct globin gene sequencing are supplanting electrophoresis as diagnostic strategies. They usually provide unambiguous identification of a sequence abnormality. However, electrophoresis is still in use in many clinical settings. Thus the aforementioned precautions in interpretation are still worth noting.

Additional sophisticated analyses of hemoglobin can be obtained from reference laboratories if detailed characterization seems warranted. For example, abnormal hemoglobin or globin bands migrating to novel positions on an isoelectric focusing gel can result from hemoglobin or globin moieties lacking heme in groups. When heme is added to the sample and the proteins are reanalyzed, these bands disappear. This behavior is nearly diagnostic of an unstable variant.

Detection of unstable hemoglobins is occasionally compromised by the selective precipitation of the unstable variant into Heinz bodies. Because most patients are heterozygotes, this phenomenon greatly reduces the apparent percentage of the variant in soluble form. Thus even a variant possessing altered electrophoretic mobility may be very difficult to detect. Indeed, some unstable hemoglobins, such as Hb Geneva or Hb Terre Haute, are so unstable that no mutant gene product can be detected in the steady state. These abnormal hemoglobins actually produce a thalassemic phenotype. They may be detectable only by isotope labeling studies or direct analysis of the globin genes.

The amino acid sequence predicted from genetic sequencing may rarely be inaccurate because of posttranslational conversion of the substituted residue into one causing an unstable hemoglobin. For example, in the first reported case of congenital Heinz body hemolytic anemia due to Hb Bristol, the DNA sequence predicts a valine-to-methionine substitution at β67. Through posttranslational

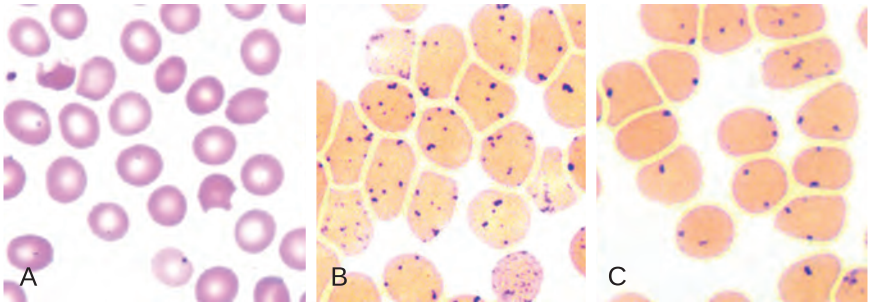

Figure 44.3 UNSTABLE HEMOGLOBINS; PERIPHERAL BLOOD SMEAR AND HEINZ BODY PREPARATION. The peripheral smear (A) shows "bite" cells with pitted-out semicircular areas of the red blood cell membrane as a result of removal of Heinz bodies by macrophages in the spleen. The Heinz body preparation (B) shows increased Heinz bodies in the same specimen, when compared with a control (C).

modification, the methionine is altered to aspartate, a hydrophilic residue that disrupts the heme pocket.

The differential diagnosis of unstable hemoglobin variants is usually straightforward if this general category of hemolytic disorders is suspected. The most common form of G6PD deficiency can also manifest with bouts of intermittent or chronic hemolysis exacerbated by oxidant drugs or infection (see Chapter 45). This diagnosis should be considered, as should other causes of chronic or intermittent hemolytic anemia, including red blood cell membrane disorders (e.g., hereditary spherocytosis) or immune hemolytic anemias (see Chapters 46 and 47). Spherocytes are relatively rare in patients with unstable hemoglobin disorders; this is sometimes a useful discriminant.

Management

The severity of the clinical complications of unstable hemoglobins varies enormously. Many patients can be managed adequately by observation and education to avoid agents that provoke hemolysis. Some patients require transfusions during bouts of severe acute hemolytic anemia. Patients who have significant morbidity because of chronic anemia or repeated episodes of severe hemolysis should be considered candidates for splenectomy, especially if hypersplenism has developed. Children with severe hemolysis may require transfusion support until they are old enough (at least 3 or 4 years of age) to undergo splenectomy without unacceptable immunologic compromise. Splenectomy is usually effective for abolition or reduction of anemia. However, splenectomy should be used only as a last resort because of the long-term risks of overwhelming sepsis and thrombosis. Infection often exacerbates hemolysis. Fever should therefore prompt close monitoring of patients for evidence of hemolysis or infection. Postsplenectomy patients with a hemolytic diathesis are also afflicted by a hypercoagulable state, probably due to the deranged membrane architecture resulting from oxidative damage to red cells no longer being cleared by the spleen. They thus require monitoring for thrombotic events and may need intermittent or long-term anticoagulant therapy.

HEMOGLOBINS WITH INCREASED OXYGEN AFFINITY

Efficient oxygen delivery by hemoglobin depends on the sigmoid shape of the hemoglobin–oxygen affinity curve. During the transition from the fully deoxygenated to the fully oxygenated state, the initial oxygenation steps occur with difficulty. In fact, the act of binding the first oxygen molecule increases the affinity of the molecule for subsequent oxygen-binding events, thus creating the sigmoid shape of the curve. The necessary intramolecular reorganization occurs only when there are the precise arrangements of hydrogen bonds, hydrophobic interactions, and the breaking and formation of salt bridges in the proper sequence (see Chapter 34).

Some mutant hemoglobins exhibiting altered oxygen affinity arise from amino acid substitutions at the interface between α- and β-chains or in regions affecting the hydrogen bonds, hydrophobic interactions, or salt bridges that influence the interaction of heme with oxygen. A second major class of mutations alters binding to 2,3-diphosphoglycerate (2,3-DPG, also known as 2,3-bisphosphoglycerate or 2,3-BPG), which in turn alters oxygen affinity when bound to hemoglobin (see Chapter 34).

Pathogenesis and Pathophysiology

High-affinity hemoglobins exhibit higher avidity for oxygen, causing the oxygen dissociation curve to shift to the left; an example is Hb Kempsey ($\beta^{99\text{Asp}\rightarrow\text{Asn}}$) (Fig. 44.4). These hemoglobins bind oxygen more readily than normal and retain more oxygen at lower partial pressure of oxygen ($P\mathrm{o}_2$) levels. They thus deliver less oxygen to tissues at normal capillary oxygen pressures. The $P\mathrm{o}_2$ in the normal lung (90 to 100 mmHg) is well above that needed to saturate hemoglobin fully with oxygen (60 mmHg). These variant hemoglobins cannot acquire any additional oxygen in the lung despite their higher affinity. However, at capillary $P\mathrm{o}_2$ (35 to 45 mmHg), high-affinity hemoglobins deliver *less* oxygen. At normal hematocrit levels, a mild tissue hypoxia results, triggering increased production of erythropoietin and red blood cells, thus resulting in polycythemia. In extreme cases, hematocrit levels of 60% to 65% can be encountered.

Many types of mutations can increase oxygen affinity. Some alter interactions within the heme pocket, others disrupt the Bohr effect or the salt-bond site, and still others impair the binding of HbA to 2,3-DPG. Loss of 2,3-DPG binding results in increases in oxygen affinity (see Chapter 34). These and numerous other examples that have been analyzed at the molecular level have greatly aided our understanding of the molecular basis for reversible oxygen binding.

Diagnosis

High-affinity hemoglobins are a cause of familial unexplained erythrocytosis (see Chapters 27, 33, and 70). Functional testing of the hemoglobin is the key to diagnosis. Oxygen affinity is usually measured as P_{50}, the $P\mathrm{o}_2$ at which hemoglobin is 50% saturated

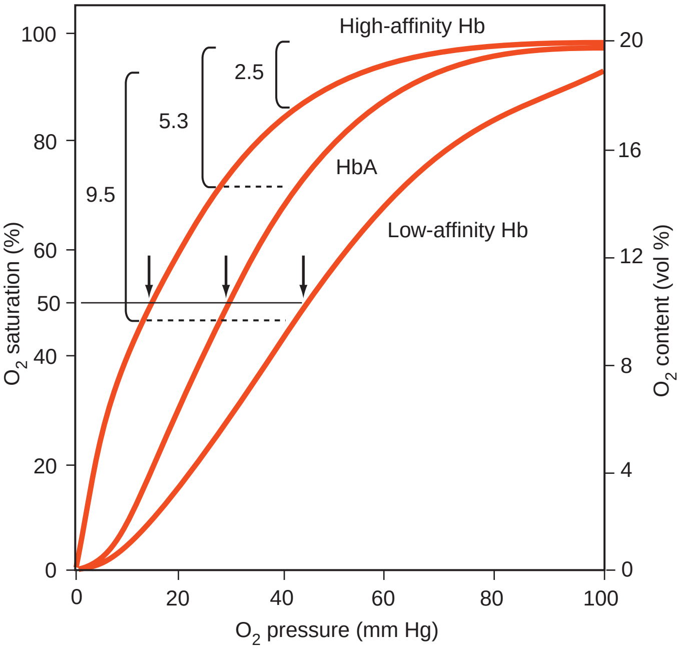

Figure 44.4 HEMOGLOBIN–OXYGEN DISSOCIATION CURVES ARE ILLUSTRATED FOR NORMAL HEMOGLOBIN (HBA) AND FOR MODEL ABNORMAL HEMOGLOBINS WITH HIGH AND LOW OXYGEN AFFINITIES. On the abscissa, the partial pressure of oxygen *(*$P\mathrm{o}_2$*)* is indicated in millimeters of mercury. On the left ordinate, the saturation of hemoglobin with oxygen is indicated as a percentage; on the right ordinate, the oxygen content of the hemoglobin is expressed as volume percent. The three inverted arrows show the $P\mathrm{o}_2$ at which the hemoglobin is 50% saturated (P_{50}) for the three hemoglobins. This value is lowest for the high-affinity hemoglobin. As the $P\mathrm{o}_2$ drops from 100 (arterial) to 40 (tissues) mmHg, hemoglobin desaturates, giving up a portion of its bound oxygen; the numbers on the brackets indicate the amount of oxygen unloaded by the three hemoglobin types expressed as volume percent. Note that the high-affinity hemoglobin delivers less than one-half the oxygen that HbA gives to the tissues, resulting in tissue anoxia, increased erythropoietin secretion, and erythrocytosis. Conversely, the low-affinity hemoglobin is even more efficient than HbA in supplying tissues with oxygen, resulting in diminished erythropoietin production and anemia. *(From Wynngaarden JB, Smith Jr LH, Bennett JC, eds. Cecil Textbook of Medicine. Philadelphia: WB Saunders; 1992.)*

with oxygen (see Fig. 44.4). The hemoglobin preparation is exposed to increasing oxygen pressures, and the relative percentages of oxyhemoglobin and deoxyhemoglobin are determined. The values are plotted on a curve, and the 50% saturation point is determined. A shift to the left means that the hemoglobin reaches 50% saturation at a lower $P\text{O}_2$. High-affinity variants are thus associated with a lower-than-normal P_{50} value. Hemoglobin electrophoresis can, but may not, reveal an abnormal band. High-performance liquid chromatography (HPLC) and DNA sequencing are better diagnostic options. In contrast to patients with polycythemia vera rubra, splenomegaly is usually absent, unless the high-affinity hemoglobin is also unstable enough to produce brisk hemolysis, in which case anemia will usually predominate, rather than polycythemia.

The most common cause of a low P_{50} value is carbon monoxide. Carbon monoxide stabilizes hemoglobin in the R "oxy" state without the need for oxygen binding. The oxygen affinity curve is therefore extremely left-shifted and is hyperbolic, rather than sigmoidal, in shape. The clinical consequences of mild chronic carbon monoxide poisoning can resemble those seen with high-affinity hemoglobin variants. The most common cause of carbon monoxide toxicity is cigarette smoking, although chronic environmental carbon monoxide exposure can elevate the hematocrit level in people such as caisson workers or tunnel toll collectors. Severe acute carbon monoxide poisoning can cause rapid death as a result of tissue hypoxia.

Management

Most patients with high-affinity hemoglobins have mild erythrocytosis; they do not require intervention. Very rarely, the hematocrit level is very high (>55% to 60%). The blood viscosity is then sufficiently elevated to require therapeutic phlebotomy. Carbon monoxide poisoning is treated with supplemental oxygen. When a patient breathes room air, the half-life of carboxyhemoglobin is 4 to 6 hours, but the half-life is 40 to 80 minutes with the use of normobaric oxygen and 15 to 30 minutes with the use of hyperbaric oxygen. Carbon monoxide detectors, designed to detect occult carbon monoxide poisoning, are now required in many municipalities and are predicted to prevent numerous fatalities from occult carbon monoxide poisoning.

HEMOGLOBINS WITH DECREASED OXYGEN AFFINITY

Pathogenesis

Low-affinity hemoglobin variants, such as Hb Kansas ($\beta^{102\text{Asn}\rightarrow\text{Thr}}$), arise from mutations that impair hemoglobin-oxygen binding or reduce cooperativity. In cases of Hb Kansas, the threonine position, β^{102}, cannot form a hydrogen bond with aspartic acid at position α^{94}. Because this aspartate residue stabilizes the R (oxy) state, Hb Kansas binds oxygen less well and exhibits a right-shifted P_{50} value (see Fig. 44.4).

Most low-affinity variants possess enough oxygen affinity to become fully saturated in the normal lung. At the low capillary $P\text{O}_2$ in other tissues, these hemoglobins deliver *higher* than normal amounts of oxygen. They become more desaturated than normal hemoglobins. Two abnormalities result from this high level of oxygen delivery. First, because tissue oxygen delivery is so "overly" efficient, normal oxygen requirements can be met by lower-than-normal hematocrit levels. This situation produces a state of "pseudoanemia," in which the low hematocrit level is deceiving because both oxygen delivery and the patients are completely normal. Second, the amount of desaturated hemoglobin circulating in capillaries and veins can be greater than 5 g/dL. Cyanosis may thus be associated with these variants. This usually ominous finding is entirely misleading in these individuals because it reflects no morbidity.

Diagnosis

Patients with unexplained anemia or cyanosis who appear to be entirely well in all other respects should be evaluated, especially if there is a positive family history. Testing for the abnormal variant follows the same reasoning as that just described for high-affinity variants. The oxygen dissociation curve will be shifted to the right, and the numeric value of the P_{50} will be higher than normal.

Management

Patients with low-affinity hemoglobins are usually asymptomatic. No treatment is required. It is important to document that a low-affinity hemoglobin is the cause of an apparent anemia or cyanosis to preempt inappropriate work-ups and provide reassurance to the patient. Cyanosis in some patients can pose a cosmetic problem, but correction with transfusions is rarely justified.

Methemoglobinemias

Methemoglobin results from oxidation of the iron moieties in hemoglobin from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Normal oxygenation of hemoglobin causes a partial transfer of an electron from the iron to the bound oxygen. Iron in this state thus resembles ferric iron and the oxygen resembles superoxide (O_2^-). Deoxygenation returns the electron to the iron, with release of oxygen. Methemoglobin forms if the electron is not returned. Methemoglobin constitutes 3% or less of the total hemoglobin in normal humans. Under normal circumstances, these levels in humans are maintained at 1% or less by the methemoglobin reductase enzyme system (the reduced form of nicotinamide adenine dinucleotide [NADH]–dehydratase, [NADH]-diaphorase, erythrocyte cytochrome b_5).

Pathogenesis and Clinical Manifestations

Methemoglobinemias of clinical interest arise by one of three distinct mechanisms: (1) globin chain mutations that result in increased formation of methemoglobin, (2) deficiencies of methemoglobin reductase, and (3) "toxic" methemoglobinemia, in which normal red blood cells are exposed to substances that oxidize hemoglobin iron to such a degree that normal reducing mechanisms are subverted or overwhelmed (see Chapter 45; Table 44.3).

Abnormal hemoglobins producing methemoglobinemia (M hemoglobins) arise from mutations that stabilize the heme iron in the ferric state. Classically a histidine in the vicinity of the heme pocket is replaced by a tyrosine (e.g., Hb M-Iwate, → β87 (F8) His → Tyr); the hydroxyl group of the tyrosine forms a complex that stabilizes the iron in the ferric state (Fig. 44.5). The oxidized heme iron is relatively resistant to reduction by the methemoglobin reductase system.

Methemoglobin has a brownish to blue color that does not revert to red on exposure to oxygen. Patients with methemoglobinemia thus

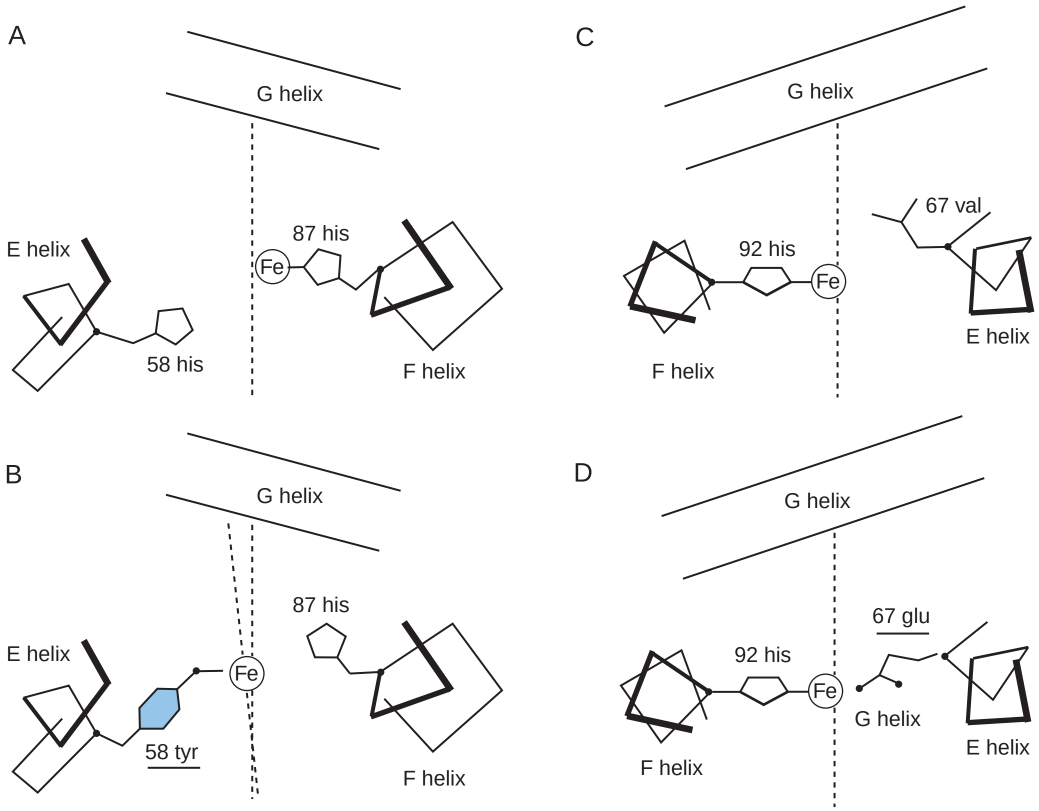

Figure 44.5 MODIFICATIONS OF THE HEME AND ITS ENVIRONMENT THAT ACCOUNT FOR TWO COMMON M HEMOGLOBINS. (A) Hemoglobin A has a His residue at the α58(E7) position. (B) In hemoglobin M-Boston, the histidine is replaced by a tyrosine, the phenolic side chain of which is capable of covalently binding to the heme iron, resulting in stabilization in the oxidized form. (C) HbA has a Val residue at position β67(E11). (D) Hb M-Milwaukee has a glutamic acid substitution for the β67 valine. The carboxylic side chain of the Glu forms a bond with iron, shifting the equilibrium toward the ferric state. *(Modified from Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA: Benjamin-Cummings; 1983. Copyright Irving Geis.)*

appear to be cyanotic. In contrast to truly cyanotic people, however, arterial partial pressure of oxygen (PaO_2) values are usually normal. Pulse oximeters will produce ambiguous results. Patients with these hemoglobins are otherwise asymptomatic because methemoglobin is usually less than 30% to 50%, the levels at which symptoms become apparent.

Hereditary methemoglobinemia resulting from methemoglobin reductase deficiency (cytochrome-b_5 reductase deficiency) is very rare. Mutations in the b_5 reductase gene cause two distinct phenotypes (see Chapter 45 for details). In cases of type I methemoglobin reductase deficiency, patients suffer solely from cyanosis; in cases of type II disease, patients manifest both cyanosis and severe mental retardation. One isoform of the b_5 reductase gene is expressed in diverse tissues for participation in a variety of cellular processes. A second isoform, produced by alternative splicing, is expressed in erythrocytes, producing a soluble protein that reduces methemoglobin. Mutations causing type I methemoglobin reductase deficiency occur throughout the gene and result in an unstable protein. Such mutations are primarily significant in erythrocytes that, without nuclei, cannot replace the degraded protein. Mutations causing type II disease occur in the critical NADH or flavin adenine dinucleotide (FAD)-binding domains, causing inactivation of the protein in all tissues and the more severe clinical phenotype.

Like patients with M hemoglobins, patients with methemoglobin reductase deficiency exhibit slate-gray “pseudocyanosis.” However, even homozygotes rarely accumulate more than 25% methemoglobin, a level compatible with minimal symptoms. Heterozygotes can have normal methemoglobin levels but are especially sensitive to agents causing methemoglobinemia.

A third toxic form of methemoglobinemia is caused by exposure to certain chemical agents and drugs that accelerate the oxidation of hemoglobin to methemoglobin (Table 44.4). Some compounds directly oxidize hemoglobin, whereas other compounds produce reactive oxygen intermediates that oxidize hemoglobin. Nitrite compounds are especially notorious and common. Some of these compounds also have a propensity to exacerbate G6PD deficiency (see Chapter 45) and the precipitation of unstable hemoglobins.

Nitrates are a frequent environmental cause of toxic methemoglobinemia. Nitrates do not directly interact with either hemoglobin or the reductase pathway but are converted to nitrites in the gut. Well water is a frequently encountered source of excessive nitrates. In general, substantial intake of these agents is required before significant amounts of methemoglobin are generated. Very young infants have lower levels of methemoglobin reductase in erythrocytes and are therefore more susceptible to these agents than are adults. However, all age groups are at risk, given sufficient exposure. Systemic acidosis, particularly in young infants suffering from diarrhea and dehydration, can also cause clinically significant methemoglobinemia.

Acquired methemoglobinemia is virtually the only situation in which life-threatening amounts of methemoglobin accumulate. In general, the only symptom produced when methemoglobin constitutes less than 30% of total hemoglobin is the cosmetic effect of cyanosis. However, as levels of methemoglobin rise to greater than 30%, patients begin to exhibit symptoms of oxygen deprivation, such as malaise, giddiness, and other alterations of mental status. The symptoms reflect a true lack of oxygen availability at the tissue level. Methemoglobin is a markedly left-shifted hemoglobin that delivers little oxygen to the tissues. When methemoglobin accounts for more than 50% of total hemoglobin, loss of consciousness, coma, and death can rapidly ensue. At this level the blood is chocolate brown.

TABLE 44.4 **Drugs and Chemicals Having Toxic Effects on Hemoglobin Molecule**

Prilocaine, benzocaine, lidocaine	+	
Menadione, naphthoquinone	+	
Naphthalene	+	
Resorcinol	+	
Phenylhydrazine	+	+

Diagnosis

Methemoglobinemia should be suspected in patients with unexplained cyanosis. It is obviously a medical emergency when any patient has cyanosis and altered mental status; a $P\text{ao}_2$ more normal than expected on the basis of the O_2 saturation should trigger a consideration of methemoglobinemia. The ingestion of nitrites as a suicidal gesture, especially in people knowledgeable with respect to chemistry, medicine, or pharmacology, should be considered. Exposure to nitrate-containing therapeutic compounds (e.g., in the setting of the intensive care unit) should also raise suspicion. Methemoglobinemia can be suspected from the brownish color of blood when it is drawn. Laboratory detection is simple; methemoglobin exhibits characteristic peaks of absorption at 630 and 502 nm, rendering it easily distinguishable from normal hemoglobin. Pulse oximetry, using a ratio of absorption at 660 nm and 940 nm, gives an inaccurate reading of 85% oxygen saturation for blood with 100% methemoglobin. The inherited M hemoglobin mutants are frequently detectable by altered electrophoretic mobility, especially if ferricyanide treatment in vitro is used to convert all the hemoglobin solution to methemoglobin.

In the case of toxic methemoglobinemia, recognition of exposure to an appropriate agent provides the most important historical clue. Acute poisoning can represent a life-threatening emergency; therefore laboratory evaluation for methemoglobin should be requested for any person displaying atypical cyanosis or cyanosis occurring along with more normal than anticipated blood gas values. Methemoglobin due to deficiencies of the reductase system can be further evaluated in reference laboratories by direct analysis of these enzymes.

Management

Patients with M hemoglobins are usually asymptomatic and require no management. The secondary cyanosis can present a cosmetic problem. The cyanosis is not reversible because ascorbic acid and methylene blue are usually ineffective.

Patients with deficiency of the reductase system usually do not require treatment. Cyanosis in these cases can be improved by treatment with oral methylene blue, 100 to 300 mg/day, or 500 mg/day of oral ascorbic acid. Riboflavin (20 mg/day) has also been reported to be effective and may be the preferred agent, because methylene blue produces discolored *(blue)* urine and ascorbic acid can cause sodium oxalate stones (see Chapter 45).

Emergency treatment of high levels of toxic methemoglobinemia begins with 1 to 2 mg/kg of intravenous methylene blue as a 1% solution in saline. It is usually infused rapidly (over 3 to 5 minutes); the dose can be repeated at 1 mg/kg after 30 minutes if necessary. This treatment is usually effective. Methylene blue acts through the reduced form of nicotinamide adenine dinucleotide (NADPH) reductase system, which in turn requires G6PD activity. The method is therefore ineffective in patients who also have G6PD deficiency. These patients or patients who are severely affected may require exchange transfusion or hyperbaric oxygen therapy. Oral ascorbic acid is not useful for emergency situations because it acts too slowly. However, follow-up maintenance management can be accomplished with either ascorbic acid or oral methylene blue. See Chapter 45 for cautionary comments about patients with pharmacologically induced serotonin deficiency.

Mild cases of methemoglobin intoxication do not require treatment. The patient can be monitored for 1 to 3 days, during which time methemoglobin levels gradually return to normal if the offending agent is eliminated. The most important follow-up therapy for patients with toxic methemoglobinemia involves a thorough search for the offending agent and its removal from the environment.

Hemoglobin Variants That Modify the Clinical Phenotypes of Thalassemia and Sickle Cell Anemia

There are a number of rare structural variants that, when coinherited with a thalassemia or sickle hemoglobin allele, create doubly heterozygous states that modify the thalassemia or sickle cell presentation. These are discussed in Chapters 41 and 42.

CHAPTER 45

RED BLOOD CELL ENZYMOPATHIES

Xylina T. Gregg and Josef T. Prchal

Red blood cells (RBCs) are highly specialized cells with the sole function of delivering oxygen to the tissues. During oxygen delivery, a highly destructive reactive oxygen species (ROS)—such as superoxide—is generated from a small fraction of the oxygen released from hemoglobin. ROS oxidizes hydroxylated sulfur groups (SH), leading to profound alterations in protein structures. This is most marked by the transformation of the hemoglobin present in high concentrations in the RBC cytoplasm to an insoluble product (i.e., Heinz bodies. ROS also damages proteins in the RBC membrane), leading to increased membrane rigidity and decreased RBC survival. In addition, ROS also oxidizes ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron, converting hemoglobin to methemoglobin, which cannot bind oxygen. In order to repair this damage and allow oxygen delivery, RBC metabolism must generate reduced nicotinamide adenine dinucleotide phosphate (NADPH) for antioxidant protection, nicotinamide adenine dinucleotide phosphate (NADH) for continuous reduction of methemoglobin to hemoglobin, 2,3-bisphosphoglycerate (2,3-BPG) to augment oxygen tissue release, and adenosine triphosphate (ATP) to fuel RBC membrane integrity and transport pathways.

During oxygen delivery, the 7-micron-sized erythrocytes must negotiate through a much smaller diameter of capillaries. The red-cell membrane accomplishes this because it is flexible yet retains its integrity and RBCs lose their intracellular organelles, including the nucleus, mitochondria, and ribosomes. However, the lack of a nucleus, ribosomes, and mitochondria means that RBCs cannot make proteins and lack more efficient ways of energy production by oxidative phosphorylation in the mitochondria. RBC enzymes allow RBCs to accomplish their tasks by supporting glycolysis and the pentose shunt and by providing protection against ROS by maintaining a high ratio of reduced glutathione (GSH) to oxidized glutathione (GSSG). Other RBC enzymes facilitate nucleotide degradation and salvage to remove toxic nucleotides from RBCs.

In non-erythroid tissues some of these same enzymes may have additional diverse functions, including roles in cell movement, cancer metastasis, apoptosis, oncogene modulation, and neurotropism. These other roles of red-cell enzymes may explain some of the non-erythroid effects of their mutations. In addition, RBCs contain enzymes, such as glutamine-oxaloacetic transaminase, erythrocyte lactate dehydrogenase (LDH), that do not have an apparent disease phenotype or any obvious physiologic function.

The activities of some RBC enzymes rapidly decrease with aging, but the activities of others decrease slowly or not at all. These age-related changes in enzyme activity impact the phenotype and biochemical testing in some enzyme deficiencies. Clinically significant abnormalities of RBC enzymes cause various hematologic phenotypes, principally acute and chronic hemolytic anemia, erythrocytosis, and methemoglobinemia. However, in rarer enzyme defects, the phenotype may be due not only to the mutant enzyme inherited, but also to other genetic, epigenetic, or environmental factors. Disorders of some RBC enzymes have no RBC phenotype, but their dysfunction in non-erythroid tissues causes glycogen storage disorders and other systemic disorders such as galactosemia. The presence of these enzymes in easily accessible RBCs serves as a convenient approach for the diagnosis of these disorders.

RBC-enzyme disorders are predominantly autosomal recessively inherited, either as homozygotes or compound heterozygotes. Two enzymes, glucose-6-phosphate dehydrogenase (G6PD), and phosphoglycerokinase are X-linked. Two others, adenosine deaminase and prolyl hydroxylase 2, are inherited in an autosomal dominant manner.

Confirmatory diagnosis of an enzyme deficiency increasingly relies on next generation sequencing and other molecular approaches of all potential genes, accounting for respective phenotypes: hemolysis, erythrocytosis, methemoglobinemia, or other typical non-erythroid phenotypes. The potential shortcomings of this testing approach and the role of biochemical testing are discussed below under specific disorders.

METABOLIC PATHWAYS

Glucose, the energy source for RBC metabolism, is used in two different pathways: glycolysis and the pentose shunt (Fig. 45.1). Glycolysis is the primary means of obtaining energy and provides up to two molecules of ATP. Glycolysis also reduces NAD to NADH, which is needed for protection of heme ferro-iron to oxidized ferri-iron (methemoglobin). The energy shunt (Rapoport-Luebering pathway) in glycolysis also generates 2,3-BPG. 2,3-BPG is an important glycolytic intermediate that facilitates hemoglobin oxygen delivery. If 2,3-BPG is formed, only one ATP molecule is generated.

Some glucose is also metabolized in the pentose shunt, which generates five and seven carbon carbohydrates and reduces NADP to NADPH, the sole source of NADPH in red cells. Under physiologic conditions, approximately 90% of glucose is consumed in the glycolytic pathway and about 10% is used in the pentose shunt. In conditions of increased oxidant stress, however, the contribution of the pentose shunt may be significantly increased.

RBCs also have an active glutathione metabolism comprised of its synthesis and reduction (Fig. 45.2). Maintaining a high ratio of GSH to its oxidized form GSSG, utilizing NADPH conversion to NADP, is the principal mechanism for protecting RBCs from ROS generated from the release of oxygen. Other lines of defense against endogenous ROS in RBCs are catalase, superoxide dismutase (SOD1), peroxiredoxin, and the active efflux of GSSG. These defense mechanisms protect the RBCs not only from ROS generated as a byproduct of released oxygen from hemoglobin but also from ROS generated by NADPH oxidase and, in reticulocytes, from mitochondria-derived ROS during oxidative phosphorylation. Non-quenched ROS is detrimental to RBCs by affecting membrane deformability and hemoglobin solubility.

ENZYMOPATHIES ASSOCIATED WITH HEMOLYTIC ANEMIA

This section discusses the deficiencies in the four RBC enzymes that account for most cases of enzymopathies associated with hemolytic anemia. The most common is G6PD deficiency, which is an enzyme essential for glutathione metabolism. G6PD deficiency may cause acute—or rarely—chronic hemolysis, depending on the mutation. Deficiencies of the three other enzymes are all associated with chronic hemolysis. Pyruvate kinase (PK) is the most common enzymopathic cause of chronic hemolysis, followed by glucose phosphate isomerase

deficiency (GPI), and pyrimidine 5′ nucleotidase-1 (P5′N1), which is essential for removal of toxic nucleotide precursors. Deficiencies of other enzymes are rarer and have highly variable clinical phenotypes that may be specific for each enzymatic defect.

Enzyme disorders affecting glutathione metabolism can cause either chronic or acute intermittent hemolysis. Heinz bodies (precipitated denatured hemoglobin) may be seen in RBCs during an acute hemolytic episode. The glycolytic enzyme deficiencies result in chronic hemolysis by a poorly understood mechanism. These patients are not subject to hemolytic crises after exposure to oxidants and their RBCs do not have any characteristic morphologic abnormalities. In contrast, marked basophilic stippling of RBCs is a hallmark of P5′N1 deficiency, which also causes chronic hemolysis. The chronic hemolytic anemia that occurs in enzyme deficiencies has been termed: hereditary non-spherocytic hemolytic anemia.

Glucose-6-Phosphate Dehydrogenase Deficiency

Introduction

G6PD deficiency was the first described and is the most common and best-studied RBC enzyme deficiency. G6PD deficiency is more common where *Plasmodium falciparum* malaria is or has been endemic. It was discovered in the 1950s as a result of investigations into a self-limited hemolysis that occurred after administration of the antimalarial drug primaquine, most commonly in individuals of African or Mediterranean ethnic origin. These early studies also determined that G6PD deficiency is X-linked. Subsequent studies in carrier females led to the discovery of X-inactivation, a phenomenon that has been exploited to study the hierarchy of hematopoiesis and the clonality of malignant neoplasms.

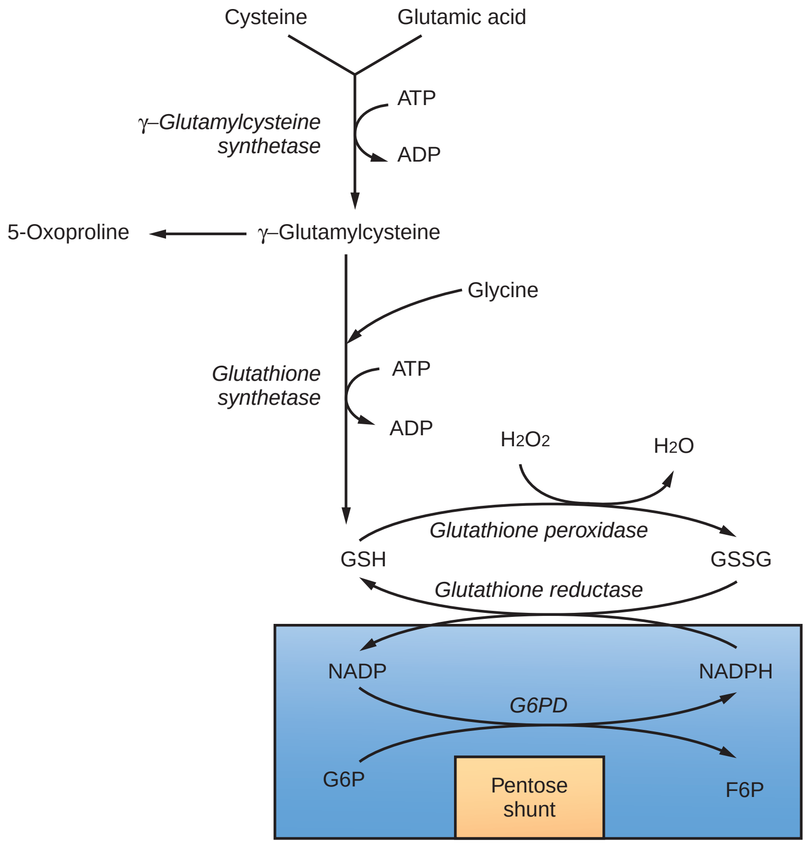

Figure 45.2 GLUTATHIONE PATHWAY. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *F6P*, fructose-6-phosphate; *G6P*, glucose-6-phosphate; *G6PD*, glucose-6-phosphate dehydrogenase; *GSH*, reduced glutathione; *GSSG*, oxidized glutathione; *NADP*, oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of nicotinamide adenine dinucleotide phosphate.

Epidemiology

G6PD deficiency is the most prevalent human enzyme deficiency in the world, affecting about 500 million people, although the vast majority of affected individuals never become symptomatic. Although most prevalent in individuals of African, Mediterranean, and southeast Asian ethnic origins, it has been found in almost every population. The highest prevalence is in the tropical belt of sub-Saharan Africa (>32%) and the Arabian Peninsula. In other populations, its prevalence ranges from less than 1 in 1000 among northern European populations to 50% of Kurdish Jews. The distribution across Asia is heterogeneous. Nearly 20% of males in Thailand are affected by one of the five prevalent variants. It is common in southern China (~5% in Hong Kong) and rare in other parts of China, while in India the prevalence varies from 0% to 27% in different regions, caste, ethnic, and linguistic groups. In the United States, G6PD deficiency affects about 10% of African American males, a lower proportion of individuals of Italian, Greek, Spanish, Corsican, and Sardinian ancestries and a variable proportion of Middle-Eastern and recent Asian immigrants. G6PD deficiency is virtually nonexistent among indigenous peoples of the Americas and Asian highlanders. The variable geographic distribution of G6PD deficiency implies that it confers a selective advantage and, as it coincides with the geographic distribution of endemic malaria, suggests protection from lethal malaria, although the exact mechanism has not been fully elucidated.

The wild-type enzyme is designated G6PD B. The most common G6PD low activity allelic variants in the United States are G6PD A– and G6PD Mediterranean; however, Asian variants are being encountered in the US population with increasing frequency. G6PD A– accounts for approximately 90% of G6PD deficient variants in Africa but is also prevalent in North and South America, the West Indies, Italy, the Canary Islands, Spain, Portugal, and the Middle East. The *G6PD A–* mutation (G202A; c.202 C>T) arose on a *G6PD A+* chromosome (A376G, c.*C376C>T*); these two missense changes are in *cis* orientation. G6PD A+ has no obvious hematologic phenotype and has a gene frequency similar to that of G6PD A– among African Americans. G6PD Mediterranean is found in highest frequencies in the southern part of Italy, Greece, Spain, Sardinia and Corsica, as well as the Middle East, Iran, and the Arabian Peninsula, India, and Indonesia. G6PD Mediterranean is not homogeneous, but is composed of several distinct mutations, which *G6PD* Mediterranean (c.C563T) predominates. Several G6PD variants are pandemic in Asia. There are more than 100 different mutations in various Asian populations.

The high frequency of the most common *G6PD* variants and the diversity of the variants suggest selection of the variants, presumably because of protection from malaria, given the geographical distribution of these variants in areas of the world where malaria is or has been endemic. However, data on which genotype confers protection from malaria and the mechanism of the protection has been conflicting. The conflicting epidemiological data may be in part due to the large number of variants and phenotypical heterogeneity. The most common African variant *G6PD A–* (c.202 C>T) and possibly other variants associated with more severe G6PD deficiency is associated with a decreased risk of cerebral malaria in male hemizygotes and female heterozygotes, but an increased risk of severe malarial anemia in male hemizygotes and female homozygotes. The mechanism of malarial protection remains to be established. However, deficient cells infested with malaria parasites appear to be phagocytized more efficiently than normal cells. The host RBCs' impaired ability to restore intracellular NADPH to maintain a high GSH/GSSG ratio may also mean that malarial parasites in G6PD-deficient RBCs are more vulnerable to ROS.

Pathobiology

G6PD is a housekeeping enzyme that catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconate in the first reaction of a pentose shunt, which reduces $NADP^+$ to NADPH (see Figs. 45.1 and 45.2). In RBCs, the pentose shunt is the only source of NADPH, which is crucial to maintaining high cellular levels of GSH to protect the cell from oxidative, stress-induced damage. Within the RBCs, oxidant injury leads to the oxidation of sulfhydryl (SH) groups on the hemoglobin molecule. This results in the formation of disulfide bridges (-S-S-), which in turn leads to decreased hemoglobin solubility and ultimately the irreversible precipitation of oxidized hemoglobin. Under normal conditions these oxidized -S-S- groups of hemoglobin and other RBC proteins are reduced by GSH to SH-groups by glutathione peroxidase, which in turn is oxidized to GSSG that is restored back to GSH by glutathione reductase in a reaction requiring NADPH. NADPH levels are maintained by G6PD, meaning in G6PD-deficient RBCs, GSH is not restored to adequate levels under oxidative stress, leading to a buildup of free radicals and insoluble hemoglobin within the cell. Precipitated hemoglobin is disruptive to the structure and function of the RBC membrane and leads to increased membrane permeability, osmotic fragility, and cell rigidity. This compromised integrity of the RBC membrane in G6PD-deficient RBCs results in extravascular hemolysis from the rapid removal of these cells within the splenic pulp and also in varying degrees of intravascular hemolysis.

The *G6PD* gene localizes to Xq28, spans 18 kb, and contains 13 exons. The active G6PD enzyme exists as a tetramer or dimer. Stability of the multimeric structures is crucial for optimal G6PD activity. G6PD activity decreases significantly as RBCs age, with a half-life of about 60 days. Reticulocytes have five times higher enzyme activity than the oldest RBC subpopulation. An even greater decrease in G6PD activity with aging is present in some mutant variants and is particularly pronounced in the African G6PD A– mutant.

G6PD variants can be divided into three categories based on the type of hemolysis they cause: acute intermittent (most common), chronic (rare), or none. The World Health Organization also classifies the different G6PD variants according to the degree of enzyme deficiency and severity of hemolysis. Class I deficiencies are the most severe and cause chronic hemolysis. Less severe G6PD Mediterranean is a class II deficiency. The even less deficient G6PD A– is a class III deficiency. Classes IV and V do not cause hemolysis and are of no clinical significance.

Over 400 variants of the G6PD enzyme have been identified by biochemical methods. However, this is likely an overestimate, as some previously described different mutations were found to be caused by the same mutation through molecular genetic studies. Currently, 237 *G6PD* mutations have been characterized by DNA sequencing in the Human Gene Mutation Database (HGMD, http://www.hgmd.org; accessed June 23, 2020); 212 of these cause disease. The majority are missense mutations but small deletions (13), splicing mutations (4), and small indels and gross deletions (4) also exist. Only one regulatory domain substitution has so far been identified. Of these mutations, at least 100 have the prevalence of a polymorphism (a rate of at least 1% in tested population). Mutations associated with chronic hemolysis tend to cluster in the vicinity of the NADP-binding domain of the *G6PD* gene and cause more severe deficiency, whereas those associated with acute intermittent hemolysis or no hemolysis are scattered throughout the gene. Unlike disease-causing mutations of other genes, total gene deletions and insertions causing frameshift and stop codon mutations are not observed. These events would be expected to be fatal, since *G6PD* is a housekeeping gene essential for basic cellular functions.

Clinical Manifestations

Acute Hemolysis

Individuals with the most common forms of G6PD deficiency have no anemia or other clinical manifestations, unless they are exposed to triggers of acute hemolysis such as oxidant drugs, infection, or ingestion of fava beans. Exposure of red cells to certain drugs results in the formation of low levels of hydrogen peroxide as the drug interacts with hemoglobin; other drugs may form other ROS that oxidize GSH without the formation of peroxide as an intermediate. Hemolysis begins in hours to 1 to 3 days after exposure to the offending drug. However, many drugs implicated in acute hemolysis in G6PD deficiency may not be true culprits because infection and other stressors can also provoke hemolysis in these people; this was elegantly reviewed by Beutler in *Blood* in 1994. In 2010 Youngster and colleagues critically evaluated extensive literature from the Cochrane database, MEDLINE, and PubMed, as well as leading pediatric, adult, pharmacology, and hematology textbooks. They concluded that solid evidence for drug-induced hemolysis in G6PD-deficient individuals exists only for these seven drugs: dapsone, methylthioninium chloride (methylene blue), nitrofurantoin, phenazopyridine, primaquine, rasburicase, and tolonium chloride (toluidine blue).

The mechanism of hemolysis induced by infection is not well understood, but the generation of hydrogen peroxide by phagocytizing leukocytes or the diffusion of oxidants from neutrophils undergoing oxidative bursts, leading to the formation of disulfide bridges of hemoglobin may be causative factors.

Depending on the G6PD variant, the duration of hemolysis can be brief or protracted. The RBCs of G6PD A- contain only 5% to 15% of the normal amount of enzyme activity and the age-dependent decline of the activity renders old RBCs severely deficient and susceptible to hemolysis. As this subpopulation is eliminated, younger RBCs and reticulocytes produced in response to hemolysis have higher G6PD activity and are typically not hemolyzed. Thus, the hemolytic process is self-limited, even when the offending agent is continued. In contrast, in G6PD Mediterranean the enzyme activity of the young RBCs is lower than in G6PD A– and hemolysis continues longer, even a few days after discontinuation of the culprit drug, albeit it is also self-limiting.

Favism

Fava beans are a staple food in many parts of the world where G6PD deficiency is found at a high gene frequency. The hemolysis precipitated by fava bean ingestion known as favism, occurs only in people who are G6PD-deficient. It is most frequently associated with the more severe G6PD Mediterranean and G6PD Cairo variants, but is also seen with lower frequency with G6PD A–. Not all individuals with G6PD Mediterranean are susceptible to favism and a tendency toward familial occurrence suggests that additional genetic factors may be important. Favism is more common in children undiagnosed with G6PD deficiency than in adults, perhaps because persons who have experienced favism are likely to avoid this exposure. Hemolysis usually occurs one to several days after fava bean consumption, but onset within the first hours after exposure has been reported.

Chronic Hemolysis

The rare G6PD variants causing chronic hemolytic anemia occur sporadically. The severity of the hemolysis ranges from mild to transfusion-dependent. Exposure to the oxidants that cause hemolysis in the acute hemolytic G6PD variants may further exacerbate hemolysis.

Neonatal Jaundice

Neonatal jaundice, which may result in kernicterus, is the most common and often the most serious consequence of G6PD deficiency. The icterus is not only caused by hemolysis but also to inadequate processing of bilirubin by the immature liver of the G6PD-deficient infant. Further, the genetically unrelated coinheritance of polymorphic UDP-glucuronosyltransferase 1 (UGT1A1) promoter alleles (Gilbert syndrome) exacerbates the icterus. Neonatal screening for G6PD deficiency and early phototherapy treatment in endemic areas has been associated with a decreased incidence of kernicterus.

Non-Erythroid Effect of Glucose-6-Phosphate Dehydrogenase Deficiency

Although patients with the common endemic G6PD variants are not at an increased risk for infections, neutrophil dysfunction has been described in some patients with rare severely deficient G6PD variants. Occasionally, cataracts have been observed in patients with some rare variants of G6PD that produce chronic hemolytic anemia. Small studies from the Middle East that remain to be confirmed suggest that decreased G6PD activity may predispose to the development of diabetes. Splenomegaly is generally not seen in G6PD-deficient individuals.

Laboratory Manifestations

Under normal conditions, most G6PD-deficient individuals are not anemic and have no laboratory evidence of hemolysis. In the setting of oxidative stress, laboratory findings indicative of acute hemolysis including anemia and reticulocytosis are seen. As the hemolysis is mainly extravascular with a variable intravascular component, variable degrees of hyperbilirubinemia, increased LDH, and decreased haptoglobin occur. Heinz bodies may be visible in the erythrocytes during an acute hemolytic episode, but not under normal circumstances. “Bite cells” have been described and purported to be indicative of G6PD deficiency, but they are not specific for G6PD deficiency and these cells are usually not present in acute hemolytic states of patients with common G6PD variants or in G6PD-deficient patients with chronic hemolysis.

Individuals with the chronic hemolytic G6PD variants have varying degrees of anemia and reticulocytosis.

Diagnosis

A biochemical diagnosis of G6PD deficiency can be made using quantitative spectrophotometric analysis to measure the generation of NADPH from NADP in RBC hemolysates. A more convenient rapid fluorescent screening test can be used to test at-risk populations. False-negative results are not unusual, however, especially if enzymatic analysis is performed during or shortly after resolution of acute hemolytic episodes, or in heterozygous females. After acute hemolysis, reticulocytes and young RBCs, which have much higher enzymatic activity, predominate. These false-negative test results are more likely to occur when a screening test rather than a quantitative spectrophotometric analysis of the enzyme activity is used. However, this obstacle can be overcome when hexokinase (HK) activity, another glycolytic enzyme with higher enzymatic activity in reticulocytes and young RBCs than in aged RBCs, is concomitantly measured; the HK/G6PD enzyme activity ratio can then be used to diagnose or rule out G6PD deficiency.

Females heterozygous for G6PD are particularly difficult to diagnose because of their mosaicism for this X-chromosome enzyme and may have total RBC enzymatic activity ranging anywhere from hemizygote to normal. However, these females have a variable mixture of deficient and nondeficient RBCs and their deficient RBCs are subject to same hemolytic destruction as those of males. Since the nucleotide substitutions of most G6PD-deficient isoenzymes have been identified, molecular diagnostic methods are more reliable for the accurate diagnosis of females who are heterozygous for G6PD deficiency and also in males with ongoing or recent acute hemolysis, or after transfusion.

Severe sporadic variants causing chronic hemolytic anemia may be considered for prenatal diagnosis in some circumstances.

Prognosis

Most patients with G6PD deficiency have normal life spans with no clinical sequelae. Neonatal icterus with resultant kernicterus that may lead to neurological deficits and mental retardation has the gravest consequences.

Therapy

Treatment of an acute hemolytic crisis includes withdrawal of any offending agent and supportive care, which in severe cases includes RBC transfusions. Folic acid supplementation is advocated for patients with chronic hemolysis, but even without folic acid supplementation, significant folate deficiency rarely occurs. Neonatal icterus associated with G6PD deficiency is treated in the same manner as neonatal icterus arising from other causes; G6PD deficiency should be considered in any neonate with hyperbilirubinemia, especially those of high-risk ethnic descent. The chronic hemolytic anemia in some exceedingly rare G6PD variants may be severe enough to require chronic transfusions and iron chelation.

Future Directions

In certain areas of the world where G6PD deficiency reaches epidemic proportions and ingestion of fava beans is staple, screening for endemic G6PD-deficient variants and avoiding fava beans in those that are G6PD deficient reduces hospitalizations and RBC transfusions. Screening of neonates in endemic areas can also reduce mortality (from kernicterus).

Pyruvate Kinase Deficiency

Introduction

PK deficiency is the most common enzyme deficiency causing hemolysis. Although this disorder is far less common than G6PD deficiency, the vast majority of patients with G6PD deficiency never suffer a hemolytic episode, while PK deficiency has a high penetrance, although also a highly variable phenotype.

Genetics

PK enzymes consist of several isoforms. They are products of two distinct genes, *PKLR* and *PKM* located on different chromosomes. *PKLR* (encoding L, liver, and R, RBC isoenzymes) is located on chromosome 1q21. The R isoform, unique to RBCs, is 33 amino acids larger than the L isoform, which is unique to hepatocytes. Expression in RBCs versus liver is due to differential use of tissue-specific promoters, which drive expression as well as tissue-specific exon usage (use of exon 1 but not exon 2 in RBCs and exon 2 but not exon 1 in liver). Regulatory elements in *PKLR*-gene expression are not fully defined, but one is a key erythroid transcription factor, Kruppel Like Factor 1 (KLF1).

The *PKM* gene encodes the M (muscle) enzymes. There are two isoforms, M1 and M2, which are different splicing products of the *PKM*-gene's single transcript. The M1 isoform is expressed in muscle, heart, brain. The M2 isoform initially predominates in fetal erythropoiesis but is progressively replaced in RBCs with the R form during fetal development. In contrast, M2 persists in leukocytes and platelets. M2 is overexpressed in many tumors and is present in other cells such as lung, fat, retina, and pancreatic islets. PKM proteins have co-stimulatory activity with hypoxia-inducible transcription factor 1 (HIF-1). The *PKM* gene is located on chromosome 15q22.

Thus far, 290 *PKLR* mutations have been characterized by DNA sequencing (Human Gene Mutation Database [HGMD, http://www.hgmd.org; accessed June 23, 2020]). Of these mutations, 276 are disease-causing, most of which are missense mutations.

Epidemiology

PK deficiency is distributed worldwide but is more common among people of northern European extraction. PK deficiency is an autosomal recessive disease, and affected patients are typically double heterozygotes, or, less commonly, homozygous for the same mutation. Homozygous mutations are usually seen in groups with marked consanguinity, and homozygous PK deficiency has been well studied in the Amish populations of Pennsylvania and Ohio and also in an isolated fundamental Mormon settlement at the Utah/Arizona border. Common mutations have well-defined geographic associations. *PKLR* c.1529 G>A mutation is the most common mutation in the United States, northern and central Europe with a population prevalence in the US of ~50/million, while c.1456 C>T is the most common mutation in southern Europe, and c.1468 C>T in Asia.

PK deficiency does not localize to geographic areas of malarial endemicity. However, there is in vitro evidence that PK deficiency provides protection against infection and replication of *Plasmodium falciparum* in human RBCs, an effect possibly mediated by reduced ATP levels in PK-deficient RBCs. PK deficiency was also shown to be protective in a mouse model of infection with *Plasmodium chabaudi*.

Pathobiology

PK enzymes catalyze the final step in glycolysis: the irreversible transfer of phosphate from phosphoenolpyruvate to adenosine diphosphate (ADP), yielding one molecule of pyruvate and one molecule of ATP (see Fig. 45.1). PK is allosterically activated by the binding of fructose 1,6-diphosphate (FDP); that is, FDP binds to a site other than the active site for substrate binding, causing a conformational change in the PK enzyme. FDP is an intermediate in the glycolytic pathway, and higher concentrations of FDP increase PK activation (a process known as feedforward stimulation). PK deficiency results in decreased glycolytic ATP production and an accumulation of glycolytic intermediates, including 2,3-BPG.

PKLR mutations affecting the active catalytic site are associated with more severe hemolytic anemia. However, the phenotypical expression of identical mutations can be strikingly different, even within the same family. Clinical PK deficiency with hemolytic anemia is largely limited to mutations of the *PKLR* gene. However, a mutation in the transcription factor *KLF1* that regulates *PKLR* transcription is a rare cause of PK deficiency (see below). Since *PKM* encoded proteins are present on leukocytes and platelets, using whole blood to analyze for PK deficiency may result in false-negative results.

PK-R exists as a heterotetramer. Since most PK-deficient patients are compound heterozygous for two different mutations, rather than homozygous for one, several different tetrameric forms of PK-R may be present, each with distinct structural and kinetic properties. This complicates genotype-to-phenotype correlations in these individuals, as it is difficult to infer which mutation is primarily responsible for deficient enzyme function and the clinical phenotype. There are even cases in which the activity of PK as measured in vitro is higher than normal, but a kinetically abnormal enzyme with low in vivo activity in erythrocytes is responsible for the hemolytic anemia. These mutations can only be detected if PK-enzyme activity is measured with and without FDP and at several concentrations of PK's substrate phosphoenolpyruvate.

PK deficiency may be also caused by mutations not directly involving the *PKLR* gene. Mutations in the erythroid transcription factor *KLF1* caused severe congenital hemolytic anemia because of a deficiency of PK. In this instance, the *PKLR* gene was intact and thus sequencing of the *PKLR* gene would miss the diagnosis of PK deficiency.

The mechanism of hemolysis in PK deficiency is not clear. The defect in ATP generation is unlikely to be the sole cause, as ATP deficiency is difficult to demonstrate in many patients and other disorders with more severe ATP deficiency are not associated with significant hemolysis. Increased apoptosis and ineffective erythropoiesis may be features of PK deficiency, although this has only been studied in splenic erythroid progenitors. Following splenectomy, despite decreased hemolysis and improved anemia, patients paradoxically have a higher number of reticulocytes, sometimes reaching over 50%. The reasons for this phenomenon is as yet unexplained.

Tolerance of Anemia

The anemia of PK deficiency is better tolerated than a comparable level of anemia seen in patients with hexokinase deficiency, since the block in glycolysis occurs after the Rapoport-Leubering shunt (see Fig. 45.1); (see section on 2,3-BPG deficiency). Levels of 2,3-BPG may be elevated up to two times normal in PK-deficient individuals, resulting in decreased hemoglobin oxygen affinity. This accumulation of 2,3-BPG shifts the oxyhemoglobin dissociation curve to the right, leading to better oxygen delivery to the tissue and improved tolerance of anemia than would be otherwise expected.

Clinical and Laboratory Manifestations

Hemolysis and Anemia

Hemolysis in PK deficiency is mainly extravascular (i.e., due to phagocytosis of cells by reticuloendothelial macrophages). However, if the hemolysis is severe, there may be spillover to intravascular hemolysis. Thus, many affected patients have normal lactate dehydrogenase (LDH) levels, but most have elevated bilirubin levels and clinical jaundice, as well as reticulocytosis. The reticulocyte count invariably increases after splenectomy.

The severity of hemolysis in PK-deficient patients is highly variable, ranging from a mild, fully compensated chronic hemolytic process without anemia, to life-threatening transfusion-requiring hemolytic anemia present at birth, to rare hydrops fetalis because of homozygosity for *PKLR* null mutations. The disease severity is often but not always similar among siblings of a given family. In most cases the degree of hemolysis declines after infancy, by a not fully understood pathophysiologic mechanism. Splenomegaly is often but not invariably present. Patients with severe hemolysis may be chronically jaundiced and may develop the clinical complications of chronic hemolytic states, including gallstones, transient aplastic anemia crises (caused by parvovirus infection), folate deficiency (rarely), extramedullary hematopoiesis and infrequently, skin ulcers. Pregnancy may precipitate hemolysis.

Iron Overload

As in any patient with ineffective erythropoiesis and hyperactive production of early RBC precursors, iron absorption is increased and iron retention in macrophages is decreased, due to erythroferrone-mediated decreases in the levels of hepcidin (see Chapters 36 and 37). Iron overload can occur, not only in transfusion-dependent patients but also in nontransfused patients, and may be severe. In some patients, clinically significant iron overload is detected in adulthood before the diagnosis of PK deficiency and chronic hemolysis.

Neonatal Icterus

Neonatal icterus may occur and is augmented by coincidental heterozygosity or homozygosity for the *UGT1A1* polymorphism.

Diagnosis

There are no characteristic RBC morphologic findings in PK deficiency; however, nonspecific changes such as echinocytes (burr cells), anisocytes, or poikilocytes may be present. PK deficiency should be suspected in patients with Coombs-negative hemolytic anemia, no RBC morphologic features of membrane disorders, and a history consistent with congenital hemolysis.

Biochemical Testing

A rapid screening test using crude hemolysate with a single concentration of substrate has been used for the detection of pyruvate deficiency but should be avoided unless leukocytes and platelets are first filtered out. PK-enzymatic screening tests also miss some *PKLR* variants.

The gold standard test for diagnosing PK deficiency is *spectrophotometric testing* of PK activity and estimation of enzyme kinetics in

RBCs free of contaminating leukocytes and platelets. In this assay, testing enzyme activity at different concentrations of the allosteric activator FDP and the substrate phosphoenolpyruvate permits detection of high Km–low-affinity mutants. However, this assay is not available at most commercial laboratories.

Genetic Testing

DNA testing for PK deficiency is increasingly available, including testing performed by commercial laboratories using heterogeneous genomic sequencing methods including next generation sequencing (NGS) of whole *PKLR* exomes or targeted sequencing. However, if a previously undescribed mutation is found, it may be challenging to determine if it is disease-causing or a rare polymorphism. If the familial genetic variant is not known, and no mutation found by NGS covering all exons, additional sequencing of flanking regions, the *PKLR* promotor, and in some instances the whole genome, may be needed. Some patients have large deletions and intronic mutations at cryptic splice sites that may not be detected by routine sequencing methods. In individuals with more than one *PKLR* mutation (compound heterozygotes), it is also important that parent samples be obtained, in order to determine whether the two mutations are present in *cis* (both from the same parent) or in *trans* (one from each parent). Identification of a deleterious mutation can facilitate testing of potentially affected family members, including prenatal testing. As the severity of hemolysis may be variable even among relatives with the same *PKLR* mutation, it is likely that in large families genetic testing will identify some affected, yet relatively asymptomatic patients, who otherwise would never be diagnosed.

However, as noted above, sequencing the *PKLR* gene will not diagnose the rare mutations of genes other than *PKLR*, such as KLF1, that have been shown to reduce PK enzymatic activity.

Therapy

Many patients do not require therapy. Some require RBC transfusions only in transient settings of increased stress, such as the perioperative period, coexistent infections, or pregnancies. However, others require chronic transfusions. Iron status should be monitored even in patients who have never been transfused. If iron overload is detected in those who are not severely anemic phlebotomy therapy, then iron chelation should be instituted.

Splenectomy has documented benefits in severe cases; the degree of hemolysis and anemia is ameliorated and the transfusion requirement is abolished or markedly decreased. The increase in hemoglobin concentration in non-transfusion-requiring patients after splenectomy ranges from 1 to 3 g/dL. It is recommended to delay splenectomy, if possible, until after the age of 3 years when the risk of infections with encapsulated organisms declines, and because in most cases the degree of hemolysis declines after infancy, by a not fully understood pathophysiologic mechanism. One PK-deficient boy with severe hemolysis was apparently cured by an allogeneic marrow transplant. Gene therapy is also actively being explored.

Mitapivat (previously called AG-348) is an orally available small molecule (a quinolone sulfonamide). It was developed using biochemical assays for compounds that could allosterically activate the PK-R enzyme similarly to FDP, but with greater efficacy. In a study in 52 patients, mitapivat increased the hemoglobin level by more than 1.0 g/dL in 26 (50% response). Responses to mitapivat correlated with the PKLR genotype and were best in individuals with missense mutations in *PKLR*. Responses did not occur (or were lower) in individuals who were homozygous for *PKLR*$^{\text{R479H}}$ or for two non-missense mutations. Of 20 individuals with a good response who continued therapy in an extension phase, 19 had a sustained increase in hemoglobin. Therapy was well-tolerated with most adverse events being grade 1 or 2 in severity. In responding patients, mitapivat was also shown to restore glycolytic pathway activity and normalize previously low ATP and previously elevated 2,3-BPG levels.

Prognosis

The clinical course is highly variable ranging from fatal hydrops fetalis, transfusion dependency from birth, and a high risk of kernicterus to normal childhood development with no or rare transfusions, or to compensated hemolysis without anemia. However, hemolysis that is fully compensated because of excessive erythropoiesis may be deceptively benign. In addition to the usual complications of chronic hemolysis such as gallstones, extramedullary hematopoiesis, and parvovirus-induced aplastic crisis, the excessive number of erythroblasts in these patients produces erythroferrone, which mediates low hepcidin and may result in typical hemochromatosis with cardiac and hepatic dysfunction.

Future Directions

New gene therapeutic techniques are being evaluated in severe PK deficiency. These include the zinc finger nucleases and *CRISPR/Cas9* technology (clustered regularly interspaced short palindromic repeats) that use noncoding RNAs to guide the Cas9 nuclease to induce site-specific DNA cleavage. Preclinical gene therapy has also been reported for PK deficiency based on a lentiviral vector harboring the promoter that drives the expression of the PKLR cDNA.

Glucose Phosphate Isomerase Deficiency

Introduction

GPI deficiency is one of the three most common RBC enzyme defects causing chronic hemolytic anemia (the other two are PK and P5’N1) with approximately 100 affected families described. Most patients are compound heterozygous for mutations that partially inactivate the enzyme.

Pathobiology

GPI converts glucose-6-phosphate to fructose-6-phosphate in the second step of glycolysis. The GPI enzyme is a homodimer and only the dimeric form has enzyme activity. The monomeric form of GPI has non-erythroid functions as a neuroleukin, i.e. a neurotrophic factor for spinal and sensory neurons and as an autocrine motility factor, which is also secreted by cancer cells and stimulates cancer metastasis. GPI also has a role in glycerolipid biosynthesis. The *GPI* gene is large (50 kb) with 18 exons and cDNA of 1.9 kb. Approximately 50 missense mutations altering the catalytic site have been reported. In some families, impaired granulocyte and neuromuscular function occurs, likely due to the non-erythroid functions of GPI.

Clinical and Laboratory Features

Most patients are compound heterozygotes, although some are homozygotes, usually as the consequence of a consanguineous union. Splenomegaly is often present. The severity of the hemolysis is variable. Many affected patients do not require therapy, other than blood transfusions during hemolytic periods, but some are transfusion dependent. In many splenectomized patients, reticulocytes increase after splenectomy, but not as strikingly as in PK deficiency; the pathophysiology of this phenomenon remains unclear.

Like any other chronic hemolytic anemia, patients are at risk for iron overload, gallstones, and for parvoviral-induced pure red-cell aplasia. Severe enzyme deficiency can be associated with hydrops fetalis, neonatal death, and neurological impairment.

In isolated GPI-deficient families, severe neuromuscular symptoms, mental retardation, and granulocyte dysfunction have been documented and dominate the disease phenotype.

Therapy

Patients may be transfused as needed. In those who are transfusion-dependent, splenectomy should be considered. Anemia significantly improves in the majority, but not all, GPI-deficient patients following splenectomy. Iron status should be monitored in all patients, even in those who have never been transfused. If iron overload is detected, iron chelation should be instituted.

Pyrimidine 5′ Nucleotidase-1 Deficiency

Introduction

P5′N1 deficiency is one of the three most common causes of chronic hemolytic anemia caused by a red cell enzymopathy. It is less common than PK deficiency but has a similar frequency as GPI deficiency. It is inherited in an autosomal recessive manner.

Pathobiology

As the reticulocyte matures, ribosomes and RNA are degraded. P5′N1 assists in the process by catalyzing the dephosphorylation of pyrimidine nucleoside monophosphates into cytidine and uridine, which can diffuse across the cell membrane. P5′N1 activity is specific for pyrimidines and is much higher in reticulocytes than mature red cells. P5′N1 activity rapidly declines during the first few days of red-cell maturation. P5′N1 activity is dependent on Mg^{2+} and is inhibited by lead (Pb^{2+}). Lead intoxication causes acquired P5′N1 deficiency with a hemolytic phenotype similar to hereditary P5′N1 deficiency.

Thus far, more than 50 different mutations in over 100 patients have been reported in P5′N1 deficiency. Most patients are homozygous and consanguinity is common.

The accumulation of pyrimidines in RBCs because of a deficiency of P5′N1 is presumed to be toxic, although the exact mechanism by which P5′N1 causes hemolysis is unknown. Deficiency of P5′N1 is at least partly compensated in vivo by other nucleosidases or other nucleotide metabolic pathways.

Clinical and Laboratory Features

P5′N1 deficiency causes chronic hemolytic anemia, with severity ranging from compensated hemolysis without anemia to transfusion-dependent anemia. Ribosomal aggregates are visible in RBCs as coarse basophilic stippling. This basophilic stippling of RBCs is a laboratory hallmark of P5′N1 deficiency, and thus morphologic examination of the peripheral blood smear provides simple and inexpensive screening. However basophilic stippling is not a specific finding, as it is also found in hemolytic anemia caused by acute lead toxicity and in some sideroblastic anemias. The nucleotides of normal red cells consist largely of purine derivatives (which have an absorption maximum at approximately 260 nm) with very low levels of pyrimidine nucleotides (absorption at 280 nm). In P5′N1 deficiency, high levels of pyrimidine nucleotides accumulate in erythrocytes, resulting in a decrease in the OD260:OD280 absorbance ratio. Confirmation of the diagnosis requires demonstration of decreased P5′N1 activity, normal blood lead levels and, if feasible, high concentrations of pyrimidine nucleotides in red cells.

Therapy

Chronic transfusion support may be necessary for severe cases. Milder cases may require transfusion only periodically during pregnancy, infection, or other stressors. Iron overload may occur, as in any chronic hemolytic condition, and iron chelation may be needed. Splenectomy was reported to be beneficial in several cases.

OTHER ENZYMOPATHIES OF THE GLUTATHIONE PATHWAY

γ-Glutamylcysteine Synthase Deficiency

γ-Glutamylcysteine synthase (GCL) catalyzes the first metabolic step of glutathione synthesis. Deficiency of this enzyme is rare. Only a few cases, usually in consanguineous families, have been reported. All patients had hemolytic anemia and approximately half also had neurologic defects, including spinocerebellar degeneration, peripheral neuropathy, and mental retardation. Some patients have been characterized at the molecular level and in all these cases the causative mutation affected the catalytic domain of GCL.

Glutathione Synthetase Deficiency

Glutathione synthetase (GS) deficiency is a slightly more common enzymopathy of glutathione metabolism than GCL deficiency. Inheritance is autosomal recessive. The clinical severity is variable, but approximately 25% of the patients die in childhood. Mild GS deficiency can manifest as only mild chronic hemolysis. Moderately affected individuals present in the neonatal period with both hemolytic anemia and severe metabolic acidosis caused by the accumulation of the γ-glutamylcysteine metabolite 5-oxoproline, which results from decreased feedback inhibition of GCL by the decreased levels of GSH. Severely affected patients have progressive neurologic defects and animal experiments suggest that 5-oxoproline has a direct neurotoxic effect. This defect may also impair skin pigmentation and one affected African American child was an albino. The different clinical manifestations are likely compounded by environmental factors as phenotypical variability among siblings with the same mutation has been encountered.

High levels of 5-oxyproline in the urine associated with metabolic acidosis (found in all severely and moderately affected but in only some of the mildly affected patients) suggest the diagnosis, which is confirmed by documenting deficiency of the enzyme or by demonstrating mutations in the *GS* gene. Correction of the metabolic acidosis and early supplementation with antioxidants such as vitamins C and E was reported to improve survival and long-term outcome in some but not all affected patients.

Patients with glutathione synthetase deficiency should avoid the same agents known to precipitate acute hemolysis in patients with G6PD deficiency.

Glutathione Reductase Deficiency

Glutathione reductase (GR) restores intracellular GSH by reducing GSSG in the presence of NADPH and flavine adenine dinucleotide (FAD), a derivative of the water-soluble vitamin riboflavin. Hereditary GR deficiency has only been reported in two Dutch families. In one consanguineous family, acute hemolytic anemia after ingestion of fava beans occurred; GR deficiency was caused by a large homozygous GR-gene deletion. The second family had a compound heterozygous mutation and a clinical phenotype of neonatal jaundice.

Riboflavin is a cofactor of GR. Mild acquired GR deficiency is common and occurs in malnourished individuals because of riboflavin deficiency but has no hematologic phenotype.

Glutathione Peroxidase Deficiency

Glutathione peroxidase is a selenium-containing enzyme that reduces hydrogen peroxide to water. Although a polymorphism affecting the activity of glutathione peroxidase and acquired decreased activity because of selenium deficiency have been described, neither was associated with a clinical phenotype.

OTHER ENZYMOPATHIES OF THE GLYCOLYTIC PATHWAY

Hexokinase Deficiency

HK catalyzes the initial step in the utilization of glucose and thus is required for both glycolysis and the pentose shunt. HK produces glucose 6-phosphate. The two main HK isoenzymes in red cells, HK1 and HKR, are the product of a single gene *HK-1* by the use of an alternate translation initiation site. HKR is unique to RBCs and reticulocytes. HKR activity is maximum in reticulocytes, while HK1 activity declines gradually. HK deficiency is a rare cause of hereditary chronic nonspherocytic hemolytic anemia with about 30 patients reported. Most patients are of northern European extraction, although one case was reported in a Chinese individual; most are compound heterozygotes. Missense mutations are most common, but deletions, splice site mutations and one mutation located in the erythroid specific promotor have been reported. These mutations were associated with variable clinical severity, ranging from mild to severe hemolytic anemia and to fetal death. A single nucleotide polymorphism in *HK-1* is associated with reduced hemoglobin and hematocrit levels in a European population. The diagnosis of HK deficiency requires demonstration of decreased HK activity; however, the biphasic decline in HK activity adds to the complexity of the assay. HK is proximal to the generation of 2,3-BPG and thus decreased levels of 2,3-BPG in HK deficiency lead to a left-shifted hemoglobin-oxygen dissociation curve and a more symptomatic anemia than comparable levels of anemia seen in patients with other RBC-enzyme deficiencies. Splenectomy may be beneficial. In a mouse model of HK deficiency, severe hemolytic anemia with extensive tissue iron deposition and marked reticulocytosis was present.

Phosphofructokinase Deficiency

Phosphofructokinase (PFK) catalyzes the rate-limiting phosphorylation of fructose-6-phosphate by ATP to FDP. PFK is a tetrameric enzyme with three types of subunits: PFKL (liver), PFKM (muscle), and PFKP (platelet). Red cells contain both M and L subunits of PFK. PFK deficiency is an autosomal recessive disorder and, in the United States, predominantly occurs in Ashkenazi Jews. Approximately 100 patients have been described, all with mutations of *PFKM*. These mutations lead to an almost complete loss of PFK activity in muscle, but only partial loss of activity in erythrocytes. Two common mutations, an intronic splice site mutation, c.237+1 G>A, and single base pair deletion, c.2003delC, are present in Ashkenazi Jews; thus, genomic screening for these mutations should facilitate diagnosis in this patient population. The most common manifestation of PFK deficiency is type VII glycogen storage disease (Tarui disease), which causes muscle weakness and exercise intolerance; a mild chronic hemolytic anemia may also be present. In some patients, hemolysis is present without muscle manifestations.

Studies of PFK deficiency in both dogs and mice demonstrated exercise intolerance, reduced lifespan, and progressive cardiac hypertrophy.

Aldolase Deficiency

Aldolase reversibly cleaves FDP into glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. Aldolase deficiency is a very rare cause of chronic non-spherocytic hemolytic anemia; myopathy and mental retardation may also occur.

Phosphoglycerokinase Deficiency

Phosphoglycerokinase catalyzes the reversible conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate, forming ATP in the process. This reaction can be bypassed by the Rappaport-Luebering shunt where 2,3 BPG is formed. Deficiency of this X-chromosome encoded enzyme is variably associated with hemolytic anemia, myopathy and myoglobinuria, mental retardation, seizures, and progressive neurological deterioration; it is suspected that other environmental, genetic, or epigenetic factors contribute to the wide range of clinical manifestations. Marrow transplant with resulting stabilization of neurological symptoms has been reported in one patient.

Triosephosphate Isomerase Deficiency

Triosephosphate isomerase (TPI) catalyzes the reversible interconversion of the triose phosphate isomers, dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. TPI deficiency is a rare autosomal recessive disorder characterized by chronic hemolytic anemia, increased susceptibility to bacterial infections, cardiomyopathy, and progressive neuromuscular disease, although the phenotype can vary even in family members with the same mutation. Neonatal jaundice may also occur. The neuromuscular disease is likely caused by the formation of toxic protein aggregates of glycated proteins formed by elevated byproducts of dihydroxyacetone phosphate.

Approximately 50 patients with several different mutations have been reported. Most patients have the same Glu104Asp mutation and are descendants from a common British/French ancestor about 1000 years ago, although the same Glu104Asp mutation was described on a different haplotype in one Spanish family. There is no effective therapy and most patients die in childhood, although there are rare exceptions.

OTHER ENZYMOPATHIES

Transaldolase Deficiency

Transaldolase catalyzes the conversion of seduhepulose-7-phosphate and glyceraldehyde-3-phosphate into erythrose-4-phosphate and fructose-6-phosphate. Transaldolase deficiency presents in the neonatal period and clinical manifestations include dysmorphic features, hepatosplenomegaly, cirrhosis, cardiac and renal abnormalities, skin manifestations, and thrombocytopenia. Hemolysis has been described in some subjects, although the phenotype is highly variable.

Adenosine Deaminase Hyperactivity

Adenosine deaminase (ADA) helps regulate the concentration of adenosine ribonucleotides in red cells by irreversibly deaminating them to inosine. Hyperactivity of ADA is a rare cause of hereditary nonspherocytic hemolytic anemia and is one of the two red-cell enzyme disorders inherited in an autosomal dominant disorder. However, the molecular mechanism of this disorder has not been identified. Deficiency of ADA is associated with severe combined immunodeficiency (see Chapter 23).

ENZYMOPATHIES ASSOCIATED WITH ERYTHROCYTOSIS

Bisphosphoglycerate Mutase Deficiency

Bisphosphoglycerate mutase (BPGM) regulates the concentration of 2,3-BPG in RBCs. 2,3-BPG is an important modifier of RBC oxygen delivery. 2,3-BPG binds to the hemoglobin tetramer and allosterically converts hemoglobin to a low oxygen affinity state, resulting in a rightward shift of the oxygen dissociation curve. BPGM is a multifunctional enzyme with both synthase and phosphatase activity. The synthase activity of BPGM converts 1,3-bisphosphoglycerate to 2,3-BPG, which is then metabolized to 3-phosphoglycerate (3-PGA), an intermediate of the glycolytic pathway, by BPGM-phosphatase (see Fig. 45.1). Deficiency of BPGM results in decreased levels of 2,3-BPG.

The consequent left shift of the oxygen dissociation curve increases hemoglobin affinity for oxygen, thus resulting in decreased delivery of oxygen into the peripheral tissues and compensatory erythrocytosis.

BPGM deficiency is rare and only two families have been comprehensively studied. In a family in France, four siblings were compound heterozygotes for two different BPGM mutations and had erythrocytosis, markedly decreased 2,3-BPG levels and undetectable BPGM activity. Some of their heterozygote relatives had a milder decrease of 2,3-BPG levels and a mild erythrocytosis. Other affected individuals have also been reported, although they have not have been as well characterized.

Cytochrome b5 Reductase Deficiency

b5R deficiency can cause erythrocytosis in association with chronic methemoglobinemia; this entity is described below.

Prolyl Hydroxylase 2 Deficiency

Prolyl hydroxylase 2 is part of the oxygen sensing pathway regulating HIFs. This enzyme is the principal component of hypoxia sensing, binds to alpha subunits of HIFs and initiates their degradation, and thus down regulates HIF-regulated genes including erythropoietin. Loss-of-function mutations of the gene encoding prolyl hydroxylase 2, *EGLN1*, cause dominantly inherited erythrocytosis. Mutations of other genes in this pathway including von Hippel-Lindau *(VHL)* and *EPAS1* mutations (encodes HIF2α) also cause congenital erythrocytosis (see Chapters 27 and 70).

ENZYMOPATHIES ASSOCIATED WITH METHEMOGLOBINEMIA

Introduction

Methemoglobinemia occurs when an imbalance arising from either increased methemoglobin production or decreased methemoglobin reduction is present. Methemoglobin is a derivative of hemoglobin in which the ferrous (Fe^{2+}) irons are oxidized to the ferric (Fe^{3+}) state. Methemoglobin is formed spontaneously at a slow rate by the autoxidation of hemoglobin. In the release of oxygen from Fe^{2+}-oxyhemoglobin, one electron is partially transferred to a small portion of released oxygen, generating superoxide and eventually forming other ROS, which convert the iron to the ferric state and form Fe^{3+}-hemoglobin, that is, methemoglobin (Fig. 45.3). Methemoglobin may also be formed from the oxidation of hemoglobin in other reactions with endogenous and exogenous compounds. The ferric hemes of methemoglobin are unable to bind oxygen and, additionally, if a ferriheme subunit is a part of a hemoglobin tetramer, the oxygen affinity of the accompanying ferrous hemes in the hemoglobin tetramer is increased. As a result, the oxygen dissociation curve is left-shifted and oxygen tissue delivery is impaired. Methemoglobin is formed continuously, but reducing mechanisms keep the methemoglobin level at about 1% of the total hemoglobin. The only physiologically important mechanism is the NADH-dependent cytochrome *b5* reductase (b5R). b5R contains a prosthetic FAD group that acts as an electron acceptor. NADH reduces FAD to FADH2, which then reduces the heme protein cytochrome *b5*. Electrons from the reduced cytochrome *b5* are in turn transferred to methemoglobin, reducing iron back to the ferrous state (see Fig. 45.3)

An alternative pathway mediated by NADPH-diaphorase uses NADPH generated by G6PD as a source of electrons to reduce redox dyes, such as methylene blue and flavin. Reduced methylene blue then reduces methemoglobin. Since these electron acceptors are not physiologic, this pathway is only of importance as it is the mechanism by which methylene blue treats acute toxic methemoglobinemia.

Epidemiology

Most cases of methemoglobinemia are acquired, resulting from increased methemoglobin formation by various exogenous agents. Acute or toxic methemoglobinemia may occur in the setting of overdose or poisoning, but also at standard doses of drugs. Acute methemoglobinemia occurs equally between males and females and over a wide range of ages; however, infants are more susceptible because their erythrocyte b5R activity is normally ~50% of adult activity.

Hereditary methemoglobinemia is most commonly caused by deficiency of b5R. b5R deficiency is an autosomal recessive condition and occurs in all racial and ethnic groups, but is endemic in certain

Figure 45.3 METHEMOGLOBINEMIA. Formation of methemoglobin and its physiologic *(open space)* and therapeutic *(shaded space)* reduction. Iron is in the ferrous state (Fe^{2+}) in oxygenated and deoxy-hemoglobin (deoxyHb). When oxygen is released, a small proportion of oxygen released from hemoglobin is converted to ROS. ROS then oxidizes bivalent ferrous iron (Fe^{2+}); to the ferric state (Fe^{3+}) (i.e., methemoglobin). NADH generated in glycolysis is a cofactor for methemoglobin reduction mediated by cytochrome b5 reductase *(b5R)* depicted in the *open space*, keeping methemoglobin at low levels (<1%). When this physiologic reduction of NADH-dependent methemoglobin reduction is either insufficient because of excessive ROS or decreased b5R activity, methemoglobin reduction can be achieved therapeutically. Exogenously administered methylene blue utilizing NADPH produced by G6PD in the pentose shunt can nonenzymatically convert methemoglobin to Fe^{2+} hemoglobin *(shaded space)*. *b5R*, Cytochrome b5 reductase; *NAD*, oxidized form of nicotinamide adenine dinucleotide phosphate; *NADH*, reduced form of NAD; *NADP*, oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of NADP; *ROS*, reactive oxygen species.

populations, including Navajo and Athabasca Native Americans and natives of Yakutsk, Siberia and is also common among Puerto Ricans. Other causes of hereditary methemoglobinemia are the autosomal dominant inheritance of an abnormal hemoglobin in hemoglobin M disease (see Chapter 44) and, very rarely, deficiency of cytochrome b5.

Pathobiology

Acute Methemoglobinemia

Many drugs and toxins have been implicated in acute methemoglobinemia. More common culprits include dapsone and local anesthetics (benzocaine, lidocaine, prilocaine). Exposure to nitrates and nitrites, widely used as food preservatives and found in well water, can also cause methemoglobinemia. Infants less than 6 months of age may have increased susceptibility to methemoglobinemia at least in part because of their lower b5R activity.

b5 Reductase Deficiency

In RBCs, b5R transfers electrons to methemoglobin to reduce it to hemoglobin. In other cells, b5R transfers electrons from cytochrome *b5* to stearoyl-CoA in the endoplasmic reticulum, a reaction that has an important role in cholesterol biosynthesis, fatty acid elongation, desaturation, and drug metabolism. There are two types of b5R deficiency. The more common type I b5R deficiency is usually caused by missense mutations leading to decreased stability of the enzyme. Thus, although b5R is abnormal in all cells, only mature RBCs, which cannot synthesize proteins and replace the enzyme, are significantly affected in patients with type I b5R deficiency. Type II b5R mutations affect the catalytic site or lead to marked structural changes and all cells have decreased b5R activity.

Clinical Manifestations

Methemoglobinemia greater than 1.5 g/dL causes clinically discernible cyanosis. Methemoglobinemia should be clinically suspected when "cyanosis," occurs in the presence of a normal arterial $P\mathrm{ao}_2$. However, cyanosis is not specific for methemoglobinemia as it can be caused by high levels of deoxygenated hemoglobin (above approximately 5 g/dL) and sulfhemoglobin (above approximately 0.5 g/dL). The hemoglobin level is also a factor in the development of cyanosis. For example, a person with an Hb of 15 g/dL and 10% methemoglobin would be cyanotic, but a person with an Hb of 10 g/dL would need at least 15% methemoglobin to become cyanotic.

Acute Methemoglobinemia

Acute methemoglobinemia is an acquired disorder caused by certain oxidant drugs and chemicals; some patients who have baseline normal methemoglobin levels but who are heterozygous for b5R deficiency (see above) are more likely develop acute methemoglobinemia. Symptoms develop in acute methemoglobinemia due to abruptly impaired tissue oxygenation. Early symptoms include headache, fatigue, dyspnea, and lethargy. At higher levels, respiratory depression, altered consciousness, shock, seizures, and death may occur. As methemoglobin levels rise above 20% to 30%, patients can experience progressive respiratory compromise, myocardial ischemia, seizures, and coma. Death typically ensues at methemoglobin levels above 70% but can occur at lower levels.

Chronic Methemoglobinemia

Individuals with *type I b5R deficiency*, which is limited to RBCs, have methemoglobin concentrations of 10% to 35% and may or may not be cyanotic but are usually asymptomatic, even with methemoglobin levels up to 40%. Life expectancy is not shortened and pregnancies occur normally. Compensatory erythrocytosis is at times observed.

In addition to methemoglobinemia and cyanosis, patients with the less common *type II b5R deficiency* exhibit mental retardation and developmental delay. Other neurologic symptoms may be present, including microcephaly, opisthotonus, athetoid movements, strabismus, seizures, and spastic quadriparesis. Life expectancy is significantly shortened and death in infancy is typical.

Laboratory Manifestations

The laboratory diagnosis of methemoglobinemia is based on analysis of its absorption spectra. A fresh specimen should always be obtained because methemoglobin levels tend to increase with storage. Traditional pulse oximetry is unreliable in the presence of methemoglobinemia because of its light absorbance properties; however, arterial or venous blood co-oximetry can determine the methemoglobin fraction along with all other substances with the optical density at 630 nm.

Methemoglobin detected by co-oximeter is optimally confirmed by the specific Evelyn-Malloy method if available. This method involves direct spectrophotometric analysis and should be used when methemoglobinemia is suspected. In the Evelyn-Malloy method, blood is lysed in a slightly acidic buffer and the optical density is measured at 630 nm before and after adding a small amount of neutralized cyanide. Absorption of methemoglobin at this wavelength disappears when it is converted to cyanmethemoglobin. This method remains the most accurate technique for the estimation of methemoglobin concentration. It also rules out spurious methemoglobinemia from extrinsic substances with an absorbance at 630 nm.

An eight-wavelength pulse oximeter, Masimo Rad-57 (the Rainbow-SET Rad-57 Pulse CO-Oximeter, Masimo Inc, Irvine, CA) has been approved by the US Food and Drug Administration and appears to be accurate for the measurement of both carboxyhemoglobin and methemoglobin.

Distinguishing the hereditary forms of congenital methemoglobinemia requires interpretation of family pedigrees as well as biochemical analyses. Cyanosis in successive generations suggests autosomal dominant hemoglobin (Hb) M disease, whereas normal parents but possibly affected siblings implies autosomal recessive b5R deficiency. Incubation of blood with methylene blue also distinguishes b5R deficiency from Hb M disease, because this treatment results in the rapid reduction of methemoglobin through the NADPH-flavin reductase pathway in cases of b5R deficiency, but not in cases of Hb M disease. Types I and II b5R deficiency are distinguished by their clinical phenotype and by analysis of enzymatic activity in erythroid and non-erythroid cells. Because the enzyme defect is found in fibroblasts, analysis of b5R activity in cultured amniotic cells for prenatal diagnosis is possible.

Differential Diagnosis

Sulfhemoglobin in concentrations greater than 0.5 gm% also causes "cyanosis," with a normal $P\mathrm{ao}_2$ and may be erroneously measured as methemoglobin. Some drugs and other pigments, including methylene blue, may also produce false-positive results when methemoglobin is measured by co-oximetry.

Prognosis

Mild acute methemoglobinemia usually resolves spontaneously in a few days. Acute methemoglobinemia that is more symptomatic, including those with respiratory or other significant compromises, generally resolves with treatment, provided if the offending cause is discontinued; however, severe cases may be fatal. Patients with type I b5R deficiency have cyanosis but a normal life expectancy, whereas the pan-deficient type II b5R patients usually succumb in childhood.

Therapy

Offending agents in cases of acquired methemoglobinemia should be discontinued. No other therapy may be required in an asymptomatic patient. However, if the patient is symptomatic or if methemoglobin levels are greater than 20%, specific therapy is indicated. Methylene blue, 1 to 2 mg/kg intravenously over 5 minutes, is an effective treatment for patients with methemoglobinemia because NADPH formed in the pentose shunt can rapidly reduce this dye to leukomethylene blue in a reaction catalyzed by NADPH diaphorase. Leukomethylene blue, in turn, nonenzymatically reduces methemoglobin to hemoglobin.

There are two exceptions to the efficacy of this treatment. In patients who are G6PD deficient, methylene blue would not only fail to give the desired effect on methemoglobin levels but might compound the impaired tissue oxygen delivery by inducing an acute hemolytic episode. Methylene blue also has monoamine oxidase inhibitor properties and thus can precipitate a potentially life-threatening serotonin syndrome in individuals receiving serotonergic agents such as selective serotonin reuptake inhibitors (SSRIs) and other serotonergic antidepressants. If methylene blue is contraindicated, ascorbic acid can be given. Patients with G6PD deficiency and acute methemoglobinemia have been successfully treated with exchange transfusion. Hyperbaric oxygen has also been used in severe cases of methemoglobinemia.

The cyanosis in hereditary b5R type I deficiency is of cosmetic significance only but can be treated with methylene blue or ascorbic acid, both of which facilitate the reduction of methemoglobin through alternate pathways. However, this therapy has no effect on the neurologic and other systemic defects seen in type II b5R deficiency.

CHAPTER 46

RED BLOOD CELL MEMBRANE DISORDERS

Patrick G. Gallagher

Characterization of the structure and function of red blood cell (RBC) membrane proteins and their genes (Fig. 46.1) has led to considerable advances in our understanding of the molecular pathology of membrane-associated disorders, including the definition and characterization of mutations of membrane proteins as a well-defined cause of hereditary hemolytic disease. Likewise, knowledge of the molecular mechanisms underlying changes in RBC deformability, structural integrity, and shape has advanced. RBC shape abnormalities often provide a clue to the pathobiology and diagnosis of the underlying disorder. This chapter categorizes RBC membrane disorders according to the following morphologic and clinical phenotypes: (1) hereditary spherocytosis (HS); (2) hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), and related disorders; (3) Southeast Asian ovalocytosis (SAO); (4) hereditary and acquired acanthocytosis; and (5) hereditary and acquired stomatocytosis (Tables 46.1 and 46.2).

VERTICAL AND HORIZONTAL INTERACTIONS OF MEMBRANE PROTEINS AND DISORDERS OF RED BLOOD CELL SHAPE

For a better understanding of the pathobiology of membrane disorders, membrane protein-protein and protein-lipid interactions are classified into two categories, vertical and horizontal interactions. Vertical interactions, which are perpendicular to the plane of the membrane, stabilize the lipid bilayer. These interactions include spectrin-ankyrin–band 3 interactions, spectrin-protein 4.1R–junctional complex proteins linkage, spectrin-ankyrin–Rh multiprotein complex linkage, and the weak interactions between the skeletal proteins and the negatively charged lipids of the inner half of the membrane lipid bilayer. Horizontal interactions, which are parallel to the plane of the membrane, support the structural integrity of erythrocytes after their exposure to shear stress. Horizontal interactions involve the spectrin heterodimer association site, where spectrin heterodimers assemble into tetramers, the principal building blocks of the membrane skeleton, and the contacts of the distal ends of spectrin heterodimers with actin and protein 4.1R within the junctional complex. Although interactions between proteins of the erythrocyte membrane are significantly more complex than can be classified by horizontal and vertical interactions, the model serves as a useful starting place for understanding erythrocyte membrane protein interactions, particularly in reference to membrane-related disorders.

According to the vertical/horizontal model, HS is considered a disorder of vertical interactions. Although the primary molecular defects in HS are heterogeneous (including deficiencies or dysfunctions of α- and β-spectrin, ankyrin, band 3, and protein 4.2), one common feature of HS RBCs is a weakening of the vertical contacts between the skeleton and the overlying lipid bilayer membrane together with its integral proteins. Consequently, the lipid bilayer membrane is destabilized, leading to the release of bilayer lipids from the cells in the form of skeleton-free lipid vesicles. This lipid loss, in turn, results in membrane surface area deficiency and spherocytosis.

In most patients with HE and the related disorder HPP (see Hereditary Elliptocytosis and Related Disorders), the principal lesion involves horizontal membrane-protein associations, primarily spectrin dimer-dimer interactions. In a subset of HE patients with a deficiency or a dysfunction of protein 4.1R or glycophorin C (GPC), the horizontal defect resides in the junctional complex, where the distal ends of spectrin tetramers connect to actin, in conjunction with protein 4.1R. In patients with severely dysfunctional spectrin mutations, the weakened spectrin dimer-dimer self-association disrupts the skeletal lattice, leading to a marked skeletal instability and cell fragments. In patients with mildly dysfunctional spectrins, the RBC shape is that of biconcave elliptocytes. It is speculated that elliptocytes are permanently deformed cells because the weakened horizontal interactions facilitate a shear stress-induced rearrangement of skeletal proteins, precluding recovery of the normal biconcave shape. This hypothesis is not applicable to all forms of elliptocytosis. For example, in SAO, the elliptocytic/ovalocytic cells containing mutant band 3 protein are rigid and "hyperstable" rather than unstable.

Acanthocytosis, Stomatocytosis, and the Bilayer Couple Hypothesis

The mechanism of acanthocytosis and stomatocytosis associated with defects of membrane proteins is much less clear. Most forms of acanthocytosis are associated with either acquired or inherited abnormalities of membrane lipids (e.g., acanthocytosis in end-stage liver disease or abetalipoproteinemia). In rare cases with acanthocytosis, membrane protein abnormalities have been detected, but the associated mechanisms leading to acanthocyte formation are unknown. These abnormalities occur in the McLeod phenotype, the chorea-acanthocytosis syndrome, and other rare disorders. In acanthocytosis erythrocytes, agents that interact with the lipids of the inner lipid bilayer leaflet normalize the shape. These studies suggest that the shape abnormalities reflect an asymmetry in the distribution of membrane lipids between the two halves of the RBC lipid bilayer as predicted by the bilayer couple hypothesis. According to the bilayer hypothesis, the shape of the RBC reflects the ratio of the surface areas of the two hemileaflets of the bilayer. The preferential expansion of the outer leaflet leads to RBC crenation (echinocytosis or acanthocytosis), whereas expansion of the inner lipid bilayer produces a cup shape (stomatocytosis) and surface invaginations.

Hereditary Spherocytosis

Introduction and Epidemiology

The typical features of HS include a dominantly inherited hemolytic anemia of mild to moderate severity, spherocytosis on the peripheral blood film, and a favorable response to splenectomy. The clinical spectrum of HS is variable and includes both mild and asymptomatic forms, as well as severe forms that appear in infancy. The previously reported HS prevalence in Western populations of 1 in 4000 persons is an underestimation because milder forms of HS might be asymptomatic, suggesting a prevalence of 1 in 2000 individuals. HS has been reported worldwide, particularly in Northern European and Japanese populations, but its prevalence in other ethnic groups is unknown.

Pathobiology

Two major factors are involved in HS pathophysiology: (1) an intrinsic RBC defect and (2) an intact spleen that selectively retains and damages abnormal HS erythrocytes. An inherited deficiency or dysfunction of proteins of the erythrocyte membrane leads to a multistep process of accelerated HS RBC destruction. Destabilization of the lipid bilayer facilitates a release of lipids from the membrane, leading to surface area deficiency and the formation of poorly deformable spherocytes that are selectively retained and damaged in the spleen.

Molecular Pathology

The molecular basis of HS is heterogeneous. Based on densitometric quantitation of membrane proteins separated by polyacrylamide gel electrophoresis, HS can be divided into the following subsets: (1) isolated deficiency of spectrin, (2) combined deficiencies of spectrin and ankyrin, (3) deficiency of band 3 protein, (4) deficiency of protein 4.2, and (5) no abnormality identified.

Isolated Spectrin Deficiency

The reported mutations of isolated spectrin deficiency include defects of both α- and β-spectrin. Mutations of the β-spectrin gene have been identified in a number of patients with dominantly inherited HS associated with spectrin deficiency. A few cases have been associated with de novo β-spectrin gene mutations. With a few exceptions, these mutations are private and may be associated with decreased β-spectrin messenger ribonucleic acid (mRNA) accumulation. Mutations in the highly conserved region of β-spectrin involved in the interaction with protein 4.1R likely lead to dysfunctional binding to protein 4.1R and thereby the linkage of spectrin to actin.

In nondominantly inherited HS associated with isolated spectrin deficiency, the defect involves α-spectrin. In normal erythroid cells, α-spectrin is synthesized in large excess of β-spectrin. Thus, patients with one normal and one defective α-spectrin allele are asymptomatic because α-spectrin production remains in excess of β-spectrin synthesis, allowing normal amounts of spectrin heterodimers to be assembled on the membrane. Patients who are homozygotes or compound heterozygotes for α-spectrin defects suffer from moderate to severe HS.

Combined Deficiency of Spectrin and Ankyrin

The biochemical phenotype of combined spectrin and ankyrin deficiency is the most common abnormality found in the erythrocytes of HS patients. Ankyrin represents the principal binding site for spectrin on the membrane; thus, it is not surprising that ankyrin deficiency is accompanied by a proportional decrease in spectrin assembly on

TABLE 46.2 Peripheral Blood Film Evaluation in a Patient With Red Cell Membrane Disorder

Shape	Pathobiology	Diagnosis
Microspherocytes	Loss of membrane lipids leading to a reduction of surface area resulting from deficiencies of spectrin, ankyrin, or band 3 and protein 4.2 Removal of membrane material from antibody-coated red cells by macrophages Removal of membrane-associated Heinz bodies, with the adjacent membrane lipids, by the spleen	HS Immunohemolytic anemias Heinz body hemolytic anemias
Elliptocytes	Permanent red cell deformation resulting from a weakening of skeletal protein interactions (such as the spectrin dimer-dimer contact). This facilitates disruption of existing protein contacts during shear stress-induced elliptical deformation. Subsequently, new protein contacts are formed that stabilize elliptical shape Unknown	Mild common HE Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Poikilocytes/fragments	Weakening of skeletal protein contacts resulting from skeletal protein mutations Unknown	Hemolytic HE/HPP Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Schistocytes, fragmented red cells	Red cells “torn” by mechanic trauma (fibrin strands, turbulent flow)	“Microangiopathic” hemolytic anemia associated with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, vasculitis, heart valve prostheses
Acanthocytes	Uptake of cholesterol and its preferential accumulation in the outer leaflet of the lipid bilayer Selective accumulation of sphingomyelin in the outer lipid leaflet Unknown	Spur cell hemolytic anemia in severe liver disease Abetalipoproteinemia Chorea-acanthocytosis syndrome, malnutrition, hypothyroidism, McLeod phenotype
Echinocytes	Expansion of the surface area of the outer hemileaflet of lipid bilayer relative to the inner hemileaflet Unknown	Hemolytic anemia associated with hypomagnesemia and hypophosphatemia in malnourished patients, pyruvate kinase deficiency; in vitro artifact of low blood storage (ATP depletion), contact with glass or elevated pH Hemolysis in long-distance runners, renal failure
Stomatocytes	Expansion of the surface area of the inner hemileaflet of the bilayer relative to the outer leaflet Unknown	Exposure of red cells to cationic anesthetics in vitro; in vivo the drug concentrations may not be sufficient to produce similar effect Alcoholism, inherited disorders of membrane permeability (hereditary stomatocytosis)
Target cells	Absolute excess of membrane lipids (both cholesterol and phospholipids: “symmetric” lipid gain), followed by an increase of cell surface area Relative excess of surface area because of a decrease in cell volume	Obstructive jaundice, liver disease with intrahepatic cholestasis Thalassemias and some hemoglobinopathies (C, D, E)

the membrane despite normal spectrin synthesis. Similar to HS associated with β-spectrin mutations, most ankyrin defects are private point mutations associated with decreased mRNA accumulation. In some cases, mutations of the ankyrin promoter leading to decreased ankyrin expression have been found. Approximately 15% to 20% of ankyrin gene mutations reported are de novo mutations.

A number of patients with atypical HS associated with karyotypic abnormalities involving deletions or translocations of the ankyrin gene locus on chromosome 8p have been described. Ankyrin deletions may be part of a contiguous gene syndrome with manifestations of spherocytosis, mental retardation, typical facies, and hypogonadism.

Deficiency of Band 3 Protein

Deficiency of band 3 protein is found in a subset of HS patients who present with a phenotype of a mild to moderate dominantly inherited HS. Most, if not all, of these patients also have concomitant protein 4.2 deficiency. Numerous band 3 mutations associated with HS have been reported, spread throughout both the cytoplasmic and the membrane-spanning domains.

A number of band 3 mutations clustered in the membrane-spanning domain that replace highly conserved arginines have been described. These arginines, which are all located at the cytoplasmic end of a predicted transmembrane helix, exhibit defective cellular trafficking from the endoplasmic reticulum to the plasma membrane.

Alleles have been identified that influence band 3 expression and that, when inherited in trans to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical severity of the disease.

Deficiency of Protein 4.2

Recessively inherited HS caused by mutations in protein 4.2 is relatively common in Japan. In these cases, an almost total absence of protein 4.2 from the erythrocyte membranes of homozygous patients

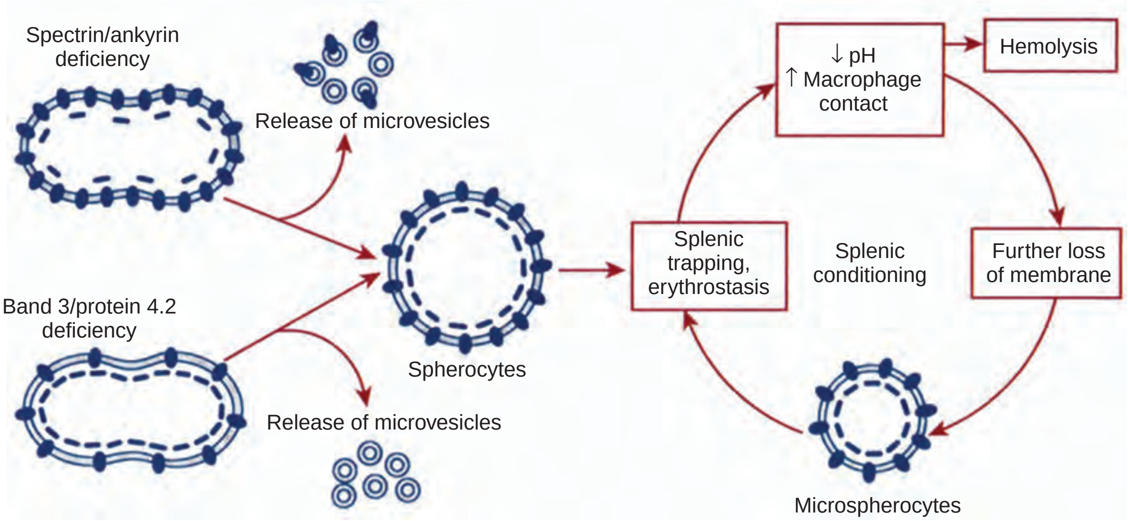

Figure 46.2 PATHOPHYSIOLOGY OF HEREDITARY SPHEROCYTOSIS. The primary defect in hereditary spherocytosis is a deficiency of membrane surface area. Decreased surface area may be produced by two different mechanisms: (1) Defects of spectrin, ankyrin, or protein 4.2 lead to reduced density of the membrane skeleton, destabilizing the overlying lipid bilayer and releasing band 3-containing microvesicles. (2) Defects of band 3 lead to band 3 deficiency and loss of its lipid-stabilizing effect. This results in the loss of band 3-free microvesicles. Both pathways result in membrane loss, decreased surface area, and formation of spherocytes with decreased deformability. These deformed erythrocytes become trapped in the hostile environment of the spleen where splenic conditioning inflicts further membrane damage, amplifying the cycle of red cell membrane injury.

is detected. Protein 4.2–deficient erythrocytes can also have a decreased content of ankyrin and band 3. Protein 4.2 deficiency also occurs in association with band 3 mutations, probably as a result of abnormal binding of protein 4.2 to the cytoplasmic domain of band 3.

A detailed listing of HS mutations is available in mutation databases maintained by the Human Gene Mutation Database (HGMD, http://www.hgmd.org).

Molecular Basis of Surface Area Deficiency

Hereditary spherocytes are intrinsically unstable, releasing lipids under a variety of in vitro conditions, including adenosine triphosphate (ATP) depletion or exposure of cells to shear stress. The loss of membrane material occurs through the release of vesicles containing integral proteins devoid of spectrin. During in vitro incubation, the loss of membrane material is sufficient to augment the surface area deficiency, as evidenced by increased osmotic fragility of the cells after incubation. It is assumed but not proved that a similar process takes place in vivo.

The molecular basis of HS is heterogeneous; thus, it is likely that surface area deficiency is a consequence of several distinct molecular mechanisms whose common denominator is either a weakening of the vertical connections between the skeleton and the lipid bilayer membrane or a weakening of the stabilizing effect of transmembrane proteins on adjacent lipid molecules of the plasma membrane. Hypothetic pathways that can lead to surface area deficiency are depicted in Fig. 46.2. In patients with isolated spectrin deficiency or a combined deficiency of spectrin and ankyrin, the loss of RBC surface may be caused by an uncoupling of the lipid bilayer membrane from the underlying skeleton. In normal RBCs, the skeleton forms a nearly monomolecular submembrane layer occupying more than one-half of the inner surface of the membrane. Consequently, spectrin deficiency leads to a decreased density of this network. As a result, areas of the lipid bilayer membrane that are not directly supported by the skeleton are susceptible to release from the cells in the form of microvesicles.

In HS associated with a deficiency of band 3 protein, two hypothetic pathways may lead to a loss of surface area. One mechanism may involve a loss of band 3 protein from the cells. Because band 3 protein spans the lipid bilayer membrane many times, it is likely that a substantial amount of "boundary" lipids are released together with the band 3 protein, thus leading to surface area deficiency. Another possible mechanism may involve a formation of band 3-free domains in the membrane, followed by the formation of membrane blebs, which are subsequently released from the cells as microvesicles. Such a hypothesis is based on the observation that aggregation of intramembrane particles (composed principally of band 3) in ghosts leads to the formation of particle-depleted domains from which membrane lipids bleb off as microvesicles. Additional evidence supporting the latter model comes from the band 3 knock-out mouse model and from human, cow, and zebrafish cases of complete band 3 deficiency. Erythrocytes lacking band 3 spontaneously shed membrane vesicles, leading to spherocytosis and hemolysis.

Alterations in Cation Content and Permeability

HS RBCs, particularly those collected from the spleen, are somewhat dehydrated and abnormally permeable to monovalent cations, presumably as a consequence of the underlying membrane defect. The cellular dehydration may be caused by activation of pathways causing a selective loss of potassium and water or a hyperactive Na^+/K^+ pump.

Entrapment of Nondeformable Spherocytes in the Spleen

The importance of the spleen in the pathophysiology of hemolysis in HS was appreciated in the original description of the disease and has been substantiated by subsequent studies. HS cells are selectively destroyed in the spleen because of their poor deformability and because of the unique anatomy of the splenic vasculature that acts as a microcirculation filter.

The poor RBC deformability is principally a consequence of a decreased cell surface/cell volume ratio resulting from the loss of surface material. Normal discocytes have an excess surface, allowing them to deform and pass through narrow microcirculation openings. In contrast, HS RBCs lack this extra surface, and their poor deformability may be further impaired by cellular dehydration.

The principal sites of RBC entrapment in the spleen are fenestrations in the wall of splenic sinuses, where blood from the splenic cords of the red pulp enters the venous circulation. In rat spleen, the length and width of these fenestrations, 2 to 3 μm and 0.2 to 0.5 μm, respectively, are approximately half the RBC diameter. Electron micrographs show that very few HS RBCs traverse these slits. Consequently, the nondeformable spherocytes accumulate in the red pulp, which becomes grossly engorged.

Splenic Conditioning and Destruction

Once trapped in the spleen, HS erythrocytes undergo additional damage or conditioning with further loss of surface area and an increase in cell density, as is evident in cells removed from the spleen at splenectomy. Some of these conditioned RBCs reenter the systemic circulation, as revealed by the "tail" of the osmotic fragility (OF) curve, indicating the presence of a subpopulation of cells with a markedly reduced surface area. After splenectomy, this RBC population disappears.

Contributions to conditioning may include a relatively low pH in the spleen as well as in the sequestered RBCs that may further compromise the poor HS RBC deformability and contact of RBCs with macrophages that may inflict additional damage on the RBC membrane. The conditioning effect of the spleen appears to represent a cumulative injury. The average residence time of HS RBCs in the splenic cords is between 10 and 100 minutes compared with 30 to 40 seconds for normal RBCs, and only 1% to 10% of blood entering the spleen is temporarily sequestered in the congested cords, whereas the remaining 90% of blood flow is rapidly shunted into the venous circulation.

Inheritance

The HS genes are assigned to several chromosomes, including chromosome 1 (α-spectrin), chromosome 8 (ankyrin), chromosome 14 (β-spectrin), chromosome 15 (protein 4.2), and chromosome 17 (band 3). In approximately two-thirds of HS patients, inheritance is autosomal dominant. In the remaining patients, inheritance is nondominant. In many of these patients, HS is caused by a de novo mutation, which is inherited in an autosomal recessive fashion in subsequent generations. Recessively inherited HS cases manifesting with severe hemolytic anemia have been reported. The majority of the affected patients were found to be severely deficient in RBC spectrin, associated with α-spectrin defects. The remaining cases characterized by a recessive inheritance pattern are caused by a defect in protein 4.2, a deficiency that is associated with relatively mild hemolysis.

Only a few cases of homozygous or "double dominant" HS have been reported. These patients have a severe hemolytic anemia, whereas their mostly consanguineous parents have a mild to moderate form of the disease or are asymptomatic.

Although the clinical severity of HS is highly variable among different kindred, in general, it is relatively uniform within a given family, in which HS is typically inherited as an autosomal dominant disorder. However, HS kindred have been described in which there was great variability in the clinical severity of affected family members. Several explanations might account for these observations, including variable penetrance of the genetic defect, a de novo mutation, presence of a mild recessive HS in the kindred, presence of a modifier allele that influences the expression of a membrane protein, or a tissue-specific mosaicism of the defect.

Clinical Manifestations

Typical Forms

The typical HS patient is relatively asymptomatic. As noted in the earliest descriptions of HS, mild jaundice can be the only symptom of the disease. Anemia is usually mild to moderate but may be absent because of compensatory bone marrow hyperplasia manifest by reticulocytosis. Splenomegaly gradually develops in most patients, with the spleen occasionally reaching large dimensions.

Mild Forms and Carrier State

In some families, anemia is absent, the reticulocyte count is normal or only minimally elevated, laboratory evidence of hemolysis is minimal or absent, and the changes in RBC shape can be mild, escaping detection on the peripheral blood film. The presence of HS is detected only by laboratory testing or during evaluation of a relative with a more symptomatic form of the disease. Some patients are first diagnosed during transient viral infections such as infectious mononucleosis or parvovirus infection, during pregnancy, or even in the 7th to 9th decades of life as the bone marrow's ability to compensate for hemolysis wanes.

Severe and Atypical Forms

The relatively uncommon patients with nondominant forms of HS can present with a severe life-threatening hemolysis early in life. Some patients can be transfusion dependent during early infancy and childhood. The underlying molecular defects include severe spectrin or band 3 deficiency.

Hereditary Spherocytosis and Nonerythroid Manifestations

In most HS cases, the clinical manifestations are confined to the erythroid lineage, probably because many of the nonerythroid counterparts of the RBC membrane proteins (e.g., spectrin and ankyrin) are encoded by separate genes or because some proteins (e.g., protein 4.1R, β-spectrin, ankyrin) are subject to tissue-specific alternative splicing. However, several HS kindred have been reported with a cosegregating neurologic or muscular abnormality, such as a degenerative disorder of the spinal cord, cardiomyopathy, or mental retardation. The observation that both erythrocyte ankyrin and β-spectrin are also expressed in muscles and the brain, particularly the cerebellum, and spinal cord raises the possibility that these HS patients may have a defect in one of these proteins. This hypothesis is further supported by studies of *nb/nb* mice, a mouse model of HS caused by an ankyrin mutation. These mice develop a neurologic syndrome with a progression that coincides with the loss of ankyrin from the Purkinje cells of the cerebellum.

Mutations of band 3 without HS have been described in patients with distal renal tubular acidosis. With a few rare exceptions, most patients with heterozygous mutations of band 3 and HS have normal renal acidification.

Laboratory Manifestations

Most HS patients have mild to moderate anemia or no anemia at all, reflecting the fact that the hemolytic rate can be very mild and that the hemolysis is fully compensated for by increased RBC production, as evidenced by reticulocytosis. Some patients, however, particularly those with nondominantly inherited HS, are severely anemic, with hemoglobin concentrations as low as 4 to 6 g/dL.

Despite the increased percentage of reticulocytes with a larger volume than mature RBCs, the mean corpuscular volume (MCV) of HS RBCs is often low normal or even slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is usually increased (>35 g/dL), together reflecting mild cellular dehydration.

The finding of an MCHC greater than 35.4 g/dL combined with an RBC distribution width (RDW) <14% has been found to be an excellent screening test for HS. Another screening method measures MCV by light scattering and provides a histogram of hyperdense erythrocytes (MCHC > 40 g/dL) claimed to identify nearly all HS patients. These hyperdense erythrocytes can be detected with newer laser-based blood counters or using aperture impedance analysis available in many clinical laboratories.

Evidence of accelerated RBC destruction, as indicated by increased lactate dehydrogenase and unconjugated bilirubin levels and by decreased haptoglobin, as well as by reticulocytosis, is present in typical HS patients. However, these abnormalities can be absent in individuals with a mild form of the disease.

Blood Film

In a typical case of HS, spherocytes are readily identified by their characteristic shape on the peripheral blood film (Fig. 46.3). They lack central pallor, their mean cell diameter is decreased, and they appear more intensely hemoglobinized, reflecting both altered RBC geometry and increased cell density. In a three-dimensional view, some spherocytes have a spherostomatocytic shape that is occasionally appreciated on the peripheral blood film. In mild forms of the disease, the peripheral blood smear can appear normal because the loss of surface area can be too small to be appreciated by blood smear evaluation; the cells appear as “fat” disks rather than as true spherocytes.

Additional morphologic features have been described in some HS patients (see Fig. 46.3). A subset of HS patients whose RBCs are deficient in band 3 protein have some pincer-like RBCs on the peripheral blood film, a finding that is both sensitive and specific for this HS subset. These pincer-like cells disappear after splenectomy. Surface spiculations or acanthocytic spherocytes have been described in cases of HS associated with defects in β-spectrin. Frequent spherovalocytes and stomatocytes have been reported in Japanese patients with protein 4.2 deficiency.

Osmotic Fragility and Eosin-5′-Maleimide Binding

Both OF testing and eosin-5′-maleimide (EMA) binding are used in evaluating HS patients.

The OF test (Fig. 46.4) measures the in vitro lysis of RBCs suspended in solutions of decreasing osmolarity. The normal RBC membrane is unstretchable and is virtually freely permeable to water. Thus, the cell behaves as a nearly perfect osmometer in that it increases its volume in hypotonic solutions progressively until a “critical hemolytic volume” is reached. At this point, the RBC membrane ruptures, and hemoglobin escapes into the supernatant solution. As a result of the loss of membrane and the ensuing surface area deficiency, the critical hemolytic volume of spherocytes is considerably lower than that of normal RBCs. Consequently, these cells hemolyze more than normal RBCs when suspended in hypotonic sodium chloride solutions. However, a finding of increased osmotic fragility is not unique to HS and is also present in other conditions associated with spherocytosis on the peripheral blood film, such as autoimmune hemolytic anemia.

The OF curve often reveals uniformly increased osmotic fragility. A “tail” of the OF curve can be present in nonsplenectomized HS patients, indicating a subpopulation of particularly fragile RBCs conditioned by splenic stasis. This subpopulation of cells disappears after splenectomy. In patients with mild HS, osmotic fragility can be normal and abnormalities can be found only after incubation that further augments the loss of surface area; however, the sensitivity of the incubated OF test can be outweighed by a loss of its specificity. The relative contributions of cell dehydration and surface area deficiency can be accurately determined by osmotic gradient ektacytometry, available in specialized laboratories.

OF testing is unreliable in patients who have small numbers of spherocytes, including those who have been recently transfused, and it is abnormal in other conditions where spherocytes are present.

The binding of EMA to band 3 and Rh-related proteins with a 1 : 1 stoichiometry in the erythrocyte membrane is the basis for the EMA binding test. After binding of fluorescently labeled EMA to erythrocyte membranes, the relative amount of fluorescence, reflecting the amount of EMA binding, is analyzed by flow cytometry. The intensity of EMA binding is decreased in HS erythrocytes (see Fig. 46.4). Although defects of band 3 protein are only found in ~25% of typical HS patients, decreased EMA fluorescence is also observed in HS erythrocytes with primary defects in ankyrin and spectrin, thought to be caused by the transmission of long-range effects of varying protein defects across the membrane, influencing EMA binding. EMA binding has high sensitivity and specificity. In laboratories with the ability to perform fluorescence-activated cell sorting-based studies, it is simple and rapidly performed, even on samples after shipment or storage.

Like osmotic fragility, EMA binding struggles in the diagnosis of mild HS where results may be normal or indeterminate. In addition, normal EMA binding has been reported in some cases of spectrin-deficient HS. Other erythrocyte abnormalities such as defects of erythrocyte hydration and variants of dyserythropoietic anemia can also yield abnormal results.

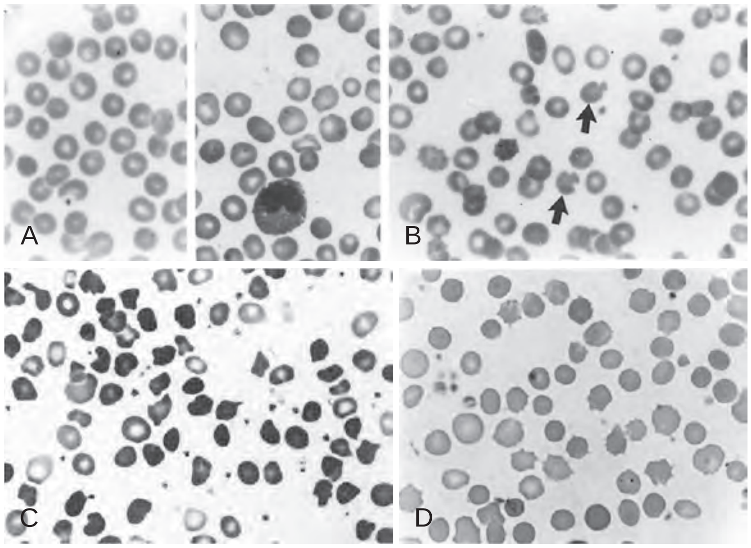

Figure 46.3 BLOOD FILMS FROM PATIENTS WITH HEREDITARY SPHEROCYTOSIS (HS) OF VARYING SEVERITY. (A) Two blood films of typical moderately severe HS with a mild deficiency of red blood cell (RBC) spectrin and ankyrin. Although many cells have a spheroidal shape, some retain a central concavity. (B) HS with pincer-like RBCs *(arrows)*, as typically seen in HS associated with band 3 deficiency. Occasional spiculated RBCs are also present. (C) Severe atypical HS caused by a severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have irregular contour. (D) HS with isolated spectrin deficiency caused by a β-spectrin mutation. Some of the spherocytes have prominent surface projections resembling sphero-acanthocytes.

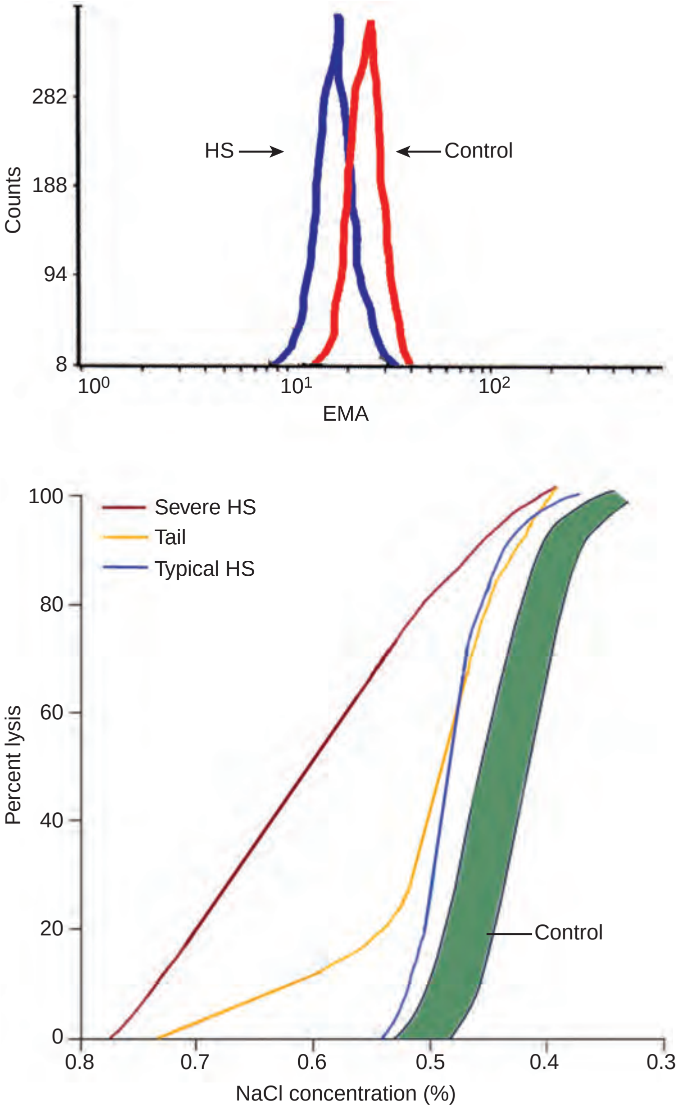

Figure 46.4 TESTING IN HEREDITARY SPHEROCYTOSIS (HS). *(Top)* Eosin-5′-maleimide (EMA) binding. EMA binding, a flow cytometric test that measures the fluorescence intensity of intact red blood cells labeled with the dye eosin-5′-maleimide that reacts with membrane band 3 protein, has been shown to be useful as a first-line test for the diagnosis of hereditary spherocytosis. Histogram of fluorescence of EMA-labeled erythrocytes from normal controls *(red)* and a patient with typical hereditary spherocytosis (HS) *(blue)*. Decreased fluorescence is observed from HS erythrocytes. *(Bottom)* Osmotic fragility (OF) curves in hereditary spherocytosis. The shaded region is the normal range. Results representative of both typical and severe spherocytosis are shown. A tail, representing fragile erythrocytes conditioned by the spleen, is common in spherocytosis patients before splenectomy. *(Reproduced with permission from Gallagher PG. Abnormalities of the erythrocyte membrane. Pediat Clin North Am. 2013;60:1349.)*

Autohemolysis and Other Tests

RBC autohemolysis, the spontaneous hemolysis of RBCs incubated under sterile conditions without glucose, was previously advocated as a sensitive test for the detection of HS. This test is being used less frequently and is probably no more sensitive than the incubated OF test. Other tests described in the literature such as the glycerol lysis test, the pink test, hypertonic cryohemolysis, and the skeleton gelation test are infrequently performed in diagnostic laboratories in the United States. The former two tests, which use glycerol to retard the osmotic swelling of RBCs, are preferred by some laboratories because they are easy to perform and can be adapted to microsamples. Cryohemolysis testing in particular remains popular in Europe.

Detection of the Underlying Molecular Defect

Because the most common finding in erythrocytes of patients with HS is a deficiency of one or more of the membrane proteins, molecular studies often include sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) solubilized RBC membrane proteins followed by densitometric quantitation. The results are expressed as ratios of individual red cell membrane proteins to band 3. This technique reveals abnormalities in approximately 70% to 80% of patients, defining the distinct biochemical phenotypes discussed previously. Direct quantitation of membrane proteins by radioimmunoassay is superior to densitometric quantitation and permits accurate measurement of the copy number of the individual proteins per RBC.

Application of molecular genetic analyses including DNA sequencing and other molecular studies complement clinical and laboratory screening and provide definitive diagnosis in most cases. Mutation detection in the major erythrocyte membrane protein genes is now available commercially. Gene-based studies are of use in diagnosing difficult cases and in cases in which a molecular diagnosis is desired. Some practitioners perform genetic diagnostic studies prior to splenectomy to ensure the correct diagnosis. Molecular analyses have potential pitfalls. In some cases, variants of unknown significance are detected, making genetic diagnosis uncertain. Mutations not detected by a study of coding regions and splice junctions may be causative, such as in distant regulatory elements, deep intronic splicing mutations, and intragenic deletions. In these cases, diagnosis is assigned based on clinical, laboratory, and biochemical findings.

Complications

Gallstones

Bilirubin stones are found in approximately 50% of patients with HS, often even in those with a very mild form of the disease. Gallstones have occasionally been detected during infancy, but they are most likely to occur in older children and young adults. The coinheritance of Gilbert syndrome increases the risk for gallstones in HS patients. Because of the high incidence of gallstones, HS patients should be periodically examined by ultrasonography for the presence of gallstones, beginning in childhood.

Crises

True hemolytic crises are relatively rare and only occasionally reported in association with infections. Aplastic crises during viral infections are largely attributable to infection by parvovirus B19. This infection (erythema infectiosum, fifth disease) manifests with fever, chills, lethargy, malaise, nausea, vomiting, abdominal pain with occasional diarrhea, respiratory symptoms, muscle and joint pains, and a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities. The virus selectively infects erythroid precursors and inhibits their growth. The ensuing anemia, often profound, can be the first manifestation of HS. Multiple family members with undiagnosed HS who are infected with parvovirus have developed aplastic crises at the same time. Infection with parvovirus is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, hydrops fetalis, and fetal demise.

Rarely, at least in developed countries, patients present with megaloblastic crises caused by folate deficiency. This typically occurs in patients with increased folate demands, such as those recovering from an aplastic crisis, pregnant women, and older adults. Megaloblastic crisis in pregnancy has been reported as the first manifestation of HS. Folate supplementation is recommended for patients with moderate to severe HS.

Other Complications

In patients with more severe forms of HS, other complications include gout, leg ulcers, or chronic dermatitis of the legs that heal after splenectomy. Symptoms of expanded erythroid space, including paravertebral or renal pelvic masses of extramedullary hematopoiesis, which can mimic an underlying neoplasm, may occur. Several cases of hemochromatosis in HS patients have been reported. In some, iron overload resulted from repeated transfusions; in others, the patients had two genetic defects, one involving HS and the other involving a hemochromatosis carrier state. Other rare complications include thrombosis, pulmonary hypertension, spinocerebellar degenerative syndromes, movement disorders, myopathy, and hypertrophic cardiomyopathy.

More than a dozen cases of HS and hematologic malignancy, including myeloproliferative disorders, multiple myeloma, and leukemia, have been reported. It is unknown if long-standing hematopoietic stress predisposes to the development of these secondary disorders or if they occurred randomly.

DIFFERENTIAL DIAGNOSIS

Because of the relatively asymptomatic presentation of HS, this diagnosis should be considered during an evaluation for unexplained splenomegaly, unconjugated hyperbilirubinemia of unknown cause, gallstones at a young age, severe anemia during pregnancy, or transient anemia during acute infections. The diagnosis of HS can be missed in mild forms of the disease because spherocytosis might not be apparent on the peripheral blood film. Autoimmune hemolytic anemia should be ruled out by negative results of a Coombs test.

More typical forms of HS, characterized by relatively uniform spherocytosis with increased MCHC, are usually easily distinguished from other disorders manifesting with spherocytosis, such as immune hemolytic anemias and unstable hemoglobins. In some patients, the spherostomatocytes in the rare Rh-null syndrome and the intermediate syndromes of hereditary stomatocytosis can be confused with HS RBCs.

Spherocytosis is transiently improved, and both the osmotic fragility and hemolysis are normalized in patients with obstructive jaundice. This is because of an expansion of RBC surface area that follows an increased uptake of phospholipids and cholesterol from the abnormal plasma lipoproteins. In normal RBCs, this leads to target cell formation; in HS, spherocytes are transformed to discocytes. Spherocytosis and the increased osmotic fragility of HS red cells are likewise improved by iron deficiency, but the RBC life span remains shortened. In addition, the coexistence of β-thalassemia trait and HS partially corrects the HS phenotype.

THERAPY AND PROGNOSIS

Splenectomy

Splenectomy is curative in almost all patients with typical forms of HS because RBC survival is normalized, and anemia and hyperbilirubinemia are corrected. Spherocytosis and the increase in osmotic fragility persist, but the tail of the OF curve, indicating the presence of a subpopulation of cells conditioned by the spleen, disappears. In patients with severe, nondominantly inherited HS, splenectomy produces a dramatic clinical improvement, but hemolysis is only partially corrected.

Several weeks to months before splenectomy, patients should be immunized with polyvalent vaccine against pneumococcus as well as vaccines against *Haemophilus influenzae* type b and meningococcus.

Indications for Splenectomy

Risks and benefits should be considered carefully in HS patients before splenectomy is performed (see box on Splenectomy for Hereditary Spherocytosis). A multitude of factors influence the decision for splenectomy in HS patients, including the risk for overwhelming postsplenectomy sepsis, the emergence of penicillin-resistant pneumococci, and the potentially increased risk for cardiovascular disease and pulmonary hypertension later in life. Indications for splenectomy include growth retardation, skeletal changes, symptomatic hemolytic disease, anemia-induced compromise of vital organs, the development of leg ulcers, or the appearance of extramedullary hematopoietic tumors. Whether to perform splenectomy in patients with moderate HS without any of these factors remains controversial.

SPLENECTOMY FOR HEREDITARY SPHEROCYTOSIS

Splenectomy is a permanently curative treatment in most cases of HS. Thus, for years, splenectomy was recommended for all HS patients regardless of the severity of anemia, gallbladder disease, or other symptoms. However, increasing concerns regarding overwhelming postsplenectomy infection (OPSI), the emergence of penicillin-resistant pneumococci, and increased risk for cardiovascular diseases have tempered these recommendations. When considering splenectomy, health care providers, the patient, and the patient's family should review and consider the risks and benefits. Individual factors that may pose additional risk, such as the distance from medical care in case of febrile illness and residence in or travel to areas where parasitic diseases such as malaria or babesiosis occur, should be considered. Expert opinions vary on indications for splenectomy. There are no studies to guide practice. However, because the risk for OPSI is highest in infancy and childhood, most agree it is best to avoid total splenectomy in early childhood.

Benefits

Anemia ameliorated
Risk for hemolysis-associated gallbladder disease eliminated
Risk for aplastic crisis eliminated

Risks

OPSI—especially with encapsulated organisms (*Streptococcus pneumoniae, Neisseria meningitides,* and *Haemophilus influenzae*)
Increased risk for thrombotic complications
Increased risk for vascular complications (pulmonary hypertension, cardiovascular disease)

Indications for Splenectomy

Expert opinions vary
Severe, symptomatic spherocytosis
Growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors (signs of severe anemia)
Older patients with vascular compromise of vital organs
Moderate HS with compensated, asymptomatic anemia: controversial; decision should be individualized

Because of an increased frequency of postsplenectomy infection in young children, most practitioners avoid splenectomy in infancy and early childhood.

Operative Considerations

When splenectomy is warranted, laparoscopic splenectomy has become the procedure of choice in many centers. Laparoscopic splenectomy has been associated with less postoperative discomfort, a quicker return to preoperative diet and activities, a shorter hospitalization time, decreased costs, and smaller scars. Early complications of splenectomy include local infection, bleeding, and pancreatitis. In general, the morbidity rate of splenectomy is lower in patients with HS than with other hematologic diseases. However, the benefits of surgery must be weighed against possible complications, such as postsplenectomy infections. Although these complications are rare and their frequency is likely to diminish further with appropriate vaccinations, the indiscriminate performance of splenectomy in all HS patients with splenomegaly is unwarranted.

Subtotal (Partial) Splenectomy

Partial splenectomy was developed for infants and young children with severe HS, anemia, and poor growth with the goals of palliating anemia and decreasing transfusion requirements while preserving splenic function. More recently, some have advocated expanding the procedure to all patients being splenectomized for HS. The goal of the operation is to decrease hemolysis while maintaining splenic phagocytic function. In initial cohorts of patients treated with partial splenectomy, stable increases in hemoglobin levels with decreased reticulocyte counts have been observed. The volume of splenic tissue left behind ranges from 10 to 30 mL. Although initial data are promising, it is not clear whether the remaining splenic tissue will effectively prevent postsplenectomy sepsis. In follow-up studies, regrowth of the splenic remnant leading to increased severity of HS and necessitating total splenectomy occurs about a third of the time.

There are no specific data to support the use of prophylactic antibiotics post splenectomy. Some practitioners avoid the prescription of prophylactic antibiotics, others recommend prophylactic antibiotics for at least 5 years post splenectomy, and others recommend their use for life.

Postsplenectomy Failures

Postsplenectomy failures are caused either by the presence of an accessory spleen missed during surgery (accessory spleens were found in 17% to 39% of all patients) or by the presence of another superimposed RBC disorder such as pyruvate kinase deficiency. The recurrence of hemolytic anemia several years after splenectomy should raise the suspicion of development of splenunculi, resulting from autotransplantation of splenic tissue during surgery. The presence of an accessory spleen or splenunculus is suggested by the absence of both Howell-Jolly bodies and the "pitted" cells with crater-like surface indentations readily seen by interference contrast microscopy. A definitive confirmation of splenosis is made by a radiocolloid liver-spleen scan or by a scan using chromium (Cr)-labeled heated RBCs, which are taken up by the ectopic splenic tissue.

Genetic Counseling

After a patient is diagnosed with HS, family members should be examined for the presence of HS. A history, physical examination for splenomegaly, complete blood count with indices, reticulocyte count, examination of the peripheral blood smear for spherocytes, and biochemical evaluation including bilirubin and haptoglobin levels should be obtained for available close relatives.

Future Directions

Advances in high-throughput DNA sequencing methodology have greatly facilitated the precise genetic diagnosis in many cases of suspected inherited membrane-associated disorders. Both targeted gene capture and whole exome sequencing have rapidly developed into effective tools for the identification of disease-causing variants in genetic disease, particularly monogenic disorders. Because they can be applied to disorders with recessive or dominant inheritance or de novo occurrence, like HS, they obviate the need for cumbersome biochemical assays and for linkage analysis in large numbers of individuals. As more patients are studied, it is likely that new HS-associated loci and modifying genes will be discovered. Identification of novel mutations will provide insight into the structure and function of associated membrane protein genes, and our understanding of genotype-phenotype relationships, particularly those with variable influence on disease severity, will be extended.

HEREDITARY ELLIPTOCYTOSIS AND RELATED DISORDERS

Introduction and Epidemiology

Hereditary elliptocytosis designates a group of inherited disorders that have in common the presence of elliptical RBCs on peripheral blood films. Elliptocytosis was first described by Dresbach in 1904, and its heritability was firmly established by Hunter. Subsequent reports have revealed a considerable heterogeneity of clinical expression and have defined several distinct syndromes, including HPP and SAO.

HE is common in people of African and Mediterranean ancestries. In the US population, the prevalence of HE is approximately 3 to 5 per 10,000. The true incidence of HE is unknown because its clinical severity is heterogeneous and most patients are asymptomatic without anemia. HE is considerably more frequent in areas of endemic malaria. In equatorial Africa, the prevalence of common HE has been estimated at between 0.6% and 1.6%. Worldwide, HE appears to be more common among people of African origin. In Southeast Asian populations, the prevalence of SAO, a variant of HE, is as high as 30%.

The molecular basis of HE remained obscure until a defect of membrane skeletal proteins was suggested. Subsequently, defects in the erythrocyte membrane proteins α-spectrin, β-spectrin, protein 4.1R, GPC, and band 3 were described.

On the basis of RBC morphologic characteristics, HE can be divided into three major groups. Common HE, a dominantly inherited condition, is morphologically characterized by biconcave elliptocytes and, in some patients, rod-shaped cells. The clinical severity of common HE is highly variable, ranging from an asymptomatic condition to a severe recessively inherited hemolytic anemia, including hemolytic HE and HPP, in which the blood film reveals numerous RBC fragments, microspherocytes, and poikilocytes. Spherocytic HE, also called hemolytic ovalocytosis, is a much less common condition in which both round "fat" ovalocytes and spherocytes are present on the blood film. SAO, a disorder highly prevalent in the malaria belt of Southeast Asia and the Pacific, is characterized by rigid, spoon-shaped cells that have either a longitudinal slit or a transverse ridge.

Pathobiology of Common Hereditary Elliptocytosis

The possibility that the primary lesion of HE and HPP erythrocytes resides in the proteins of the RBC membrane skeleton was first raised by the findings of thermal instability of HPP spectrin, retention of the elliptical shape in HE membrane skeletons, disintegration of membrane skeletons after exposure to shear stress, defective self-association of spectrin dimers to tetramers, altered susceptibility of spectrin to tryptic digestion, and a deficiency of the membrane skeleton proteins spectrin and protein 4.1R. Gene cloning and determination of the primary structure of these proteins was soon followed by reports of mutations in the genes encoding erythrocyte membrane proteins.

Spectrin Mutations

The most common defects in HE, found in approximately two-thirds to three-quarters of all patients, are mutations of α- or β-spectrin. Both α- and β-spectrin are elongated flexible molecules consisting of triple-helical repeats connected by nonhelical segments. These polypeptides are associated side to side in an antiparallel position, forming a flexible, rod-like αβ heterodimer in which the NH_2-terminal of α-spectrin and the COOH-terminal of β-spectrin form the head region of the heterodimer. Spectrin heterodimers associate head to head to form spectrin tetramers, the major structural subunits of the membrane skeleton. Spectrin tetramers in turn are interconnected into a highly ordered two-dimensional lattice through binding, at their distal ends, to actin oligomers with the aid of protein 4.1R.

The contact site between the α- and β-spectrin chains of the opposed heterodimers is a combined "atypical" triple-helical repetitive segment in which the first two helices are contributed by the COOH-terminal of β-spectrin, whereas helix 3 is the first helical segment of α-spectrin. Spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that under physiologic conditions strongly favors spectrin tetramers. Most α-spectrin defects are at or near the NH_2-terminal of α-spectrin, which is involved in the heterodimer contact (the αI domain defined by limited tryptic peptide mapping; see the discussion under Laboratory Manifestations), and impair the self-association of spectrin into tetramers. Most α-spectrin mutations are point mutations. These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin.

Elliptocytogenic β-spectrin mutations are COOH-terminal point mutations or truncations that disrupt the formation of the combined β triple-helical repetitive segment and consequently the self-association of spectrin heterodimers to tetramers. All of these mutations open a proteolytic cleavage site residing in the third helix of the combined repetitive segment, giving rise to a 74-kDa αI peptide.

Although most spectrin mutations reside in the vicinity of the αβ-spectrin self-association site, a few mutations remote from the self-association site have been described. These mutations are asymptomatic in the simple heterozygous state but cause hemolytic anemia, which can be severe, in homozygous patients. Unlike mutations located in the self-association contact site, which are predicted to disrupt the conformation of the local protein structure, mutations outside this region are predicted to perturb long-range protein-protein interactions, disrupting the positively coupled, cooperative interactions of αβ spectrin self-association, spectrin-ankyrin interactions, and ankyrin–band 3 interactions. One HE-associated mutation in a linker region remote from the self-association contact site disrupted the stability propagated from one spectrin repeat to the next.

Protein 4.1R Mutations

Another group of elliptocytogenic mutations, although much less common than spectrin mutations, are quantitative or qualitative defects of protein 4.1R. Protein 4.1R is a multifunctional protein that contains several important sites of protein interactions, including the spectrin-binding domain, where 4.1R binds to the distal end of the spectrin αβ heterodimer, markedly increasing the binding of spectrin to oligomeric actin, and the basic NH_2-terminal domain, where 4.1R interacts with GPC, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of spectrin to the membrane.

Studies of 4.1R mRNA from normal RBCs revealed 4.1R isoforms resulting from complex tissue- and developmental stage-specific patterns of alternate mRNA splicing. Alternate translation initiation sites are present in the protein 4.1R mRNA. When an upstream initiator methionine is used, isoforms greater than 80kDa are synthesized. During erythropoiesis, this upstream initiator methionine is spliced out and a downstream initiator methionine is used, leading to the production of the 80-kDa mature erythroid protein 4.1R isoform. On SDS-PAGE, protein 4.1R is resolved into two bands of different sizes: 4.1a and 4.1b. The larger band, 4.1a, is typically found in normal RBCs, whereas the shorter one, 4.1b, represents the major isoform of reticulocytes. The 4.1b isoform is converted into the 4.1a isoform by deamidation of Asn 502.

A partial deficiency of protein 4.1R is associated with mild, dominantly inherited HE, whereas a complete deficiency (a homozygous state) leads to a severe hemolytic disease. Homozygous protein 4.1R(−) erythrocytes fragment more rapidly than normal at moderate shear stresses, an indication of their intrinsic instability. Membrane mechanic stability can be restored by reconstituting the deficient RBCs with protein 4.1R or the protein 4.1R/spectrin/actin-binding site. Homozygous protein 4.1R(−) erythrocytes also lack p55 and have only 30% of the normal content of GPC. These homozygous protein 4.1R(−) erythrocytes, as well as GPC-deficient Leach erythrocytes, demonstrate decreased invasion and growth of *Plasmodium falciparum* in vitro.

Mutations associated with protein 4.1R deficiency have included deletions that include the exon encoding the erythroid transcription start size and mutations of the transcription initiation codon. Qualitative defects of protein 4.1R protein include deletions and duplications of the exons encoding the spectrin-binding domain, leading either to truncated or elongated forms of protein 4.1R. Electron microscopic studies of homozygous protein 4.1R(−) erythrocyte membranes revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, suggesting that protein 4.1R plays an important role in maintenance not only of the skeletal network but also of the integral proteins of the membrane structure.

Glycophorin C Deficiency

GPC has been found absent because of a variety of molecular defects. In contrast to other forms of HE, which are dominantly inherited, heterozygous carriers are asymptomatic, with normal RBC morphology, and homozygous patients have no anemia and only mild elliptocytosis apparent on the peripheral blood film.

GPC deficiency with elliptocytosis, the so-called Leach phenotype, caused by reduced expression of GPC, should be distinguished from the immunochemically defined phenotypes Gerbich and Yus, in which abnormal glycoproteins are formed that can functionally substitute for normal GPC and preserve the normal RBC shape. The Leach phenotype is usually caused by a large deletion of genomic DNA (~7 kb) that removes exons 3 and 4 from the GPC/glycophorin D locus. In one patient, the Leach phenotype was caused by a frameshift mutation.

GPC-deficient patients are also partially deficient in protein 4.1R and lack p55, presumably because these proteins form a complex and recruit or stabilize each other on the membrane. It has been speculated that the protein 4.1R deficiency in Leach erythrocytes is the cause of the elliptocytic shape. In contrast, patients deficient in glycophorin A, the major transmembrane glycoprotein, are asymptomatic.

Membrane Effects

Most of the elliptocytogenic mutations of spectrin reside within, or in the vicinity of, the spectrin heterodimer self-association site, disrupting this region and consequently disrupting the two-dimensional integrity of the membrane skeleton (Fig. 46.5). These defects are detected by ultrastructural examination of the membrane skeleton, revealing disruption of a normally uniform hexagonal lattice. Consequently, membrane skeletons are mechanically unstable, as are whole cell membranes and the cells. In patients with severely dysfunctional spectrin mutations or patients homozygous or doubly heterozygous for spectrin mutations, the membrane instability is sufficient to cause RBC fragmentation with hemolytic anemia under conditions of normal circulatory shear stress.

The pathobiology of the elliptocytic shape is less clear. RBC precursors in common HE are round and the cells become progressively more elliptical as they age in vivo. RBCs subjected to shear stress in vitro, or RBCs flowing through microcirculation in vivo, have an elliptical or parachute-like shape, respectively. It is possible that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape because the weakened spectrin heterodimer contacts facilitate skeletal reorganization, which follows axial deformation of cells resulting from application of a prolonged or excessive shear stress. This reorganization is likely to involve breakage of the unidirectionally stretched protein connections followed by the formation of new protein contacts that preclude the recovery of a normal biconcave shape. This process has been shown to account for the permanent deformation of irreversibly sickled cells.

In HPP, the recessively inherited form of HE characterized by severe hemolysis, RBCs have two abnormalities. They contain a mutant spectrin that characteristically disrupts spectrin heterodimer self-association, and they are also partially deficient in spectrin, as evidenced by a decreased spectrin/band 3 ratio. In some HPP cases, this biochemical phenotype is a consequence of a double heterozygous state for an elliptocytogenic α-spectrin mutation and a defect involving reduced α-spectrin synthesis. Such synthetic defect of α-spectrin is fully asymptomatic in the heterozygous carrier because under normal conditions, the synthesis of α-spectrin is approximately three to four times greater than that of β-spectrin.

When present in conjunction with an elliptocytogenic mutation of α-spectrin, such a synthetic defect augments the expression of the

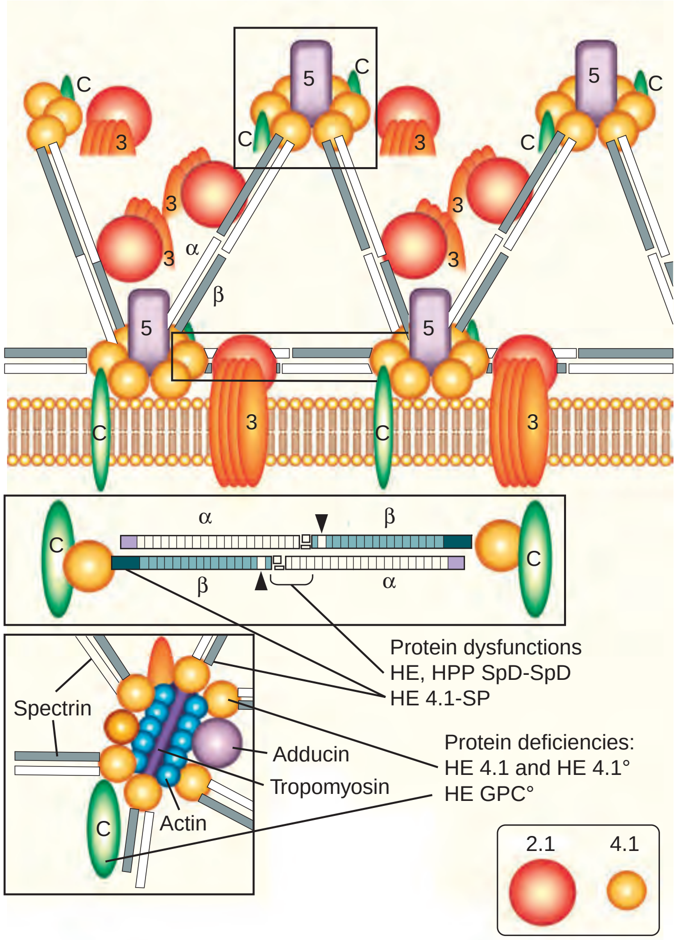

Figure 46.5 SCHEMATIC REPRESENTATION OF THE MOLECULAR ASSEMBLY OF THE MEMBRANE SKELETON AND THE MOLECULAR DEFECTS IN HEREDITARY ELLIPTOCYTOSIS (HE) AND HEREDITARY PYROPOIKILOCYTOSIS (HPP). Spectrin is composed of α- and β-spectrin heterodimers (SpD) that associate in their head regions into tetramers. At their distal ends, SpD bind to the junctional complexes of oligomeric actin (band 5 *[5]*) and protein 4.1. Additional proteins found in the junctional complex, such as adducin and tropomyosin, are shown in the lower enlarged area. The membrane skeleton is attached to transmembrane proteins by interactions of β-spectrin with ankyrin (protein 2.1; *[black arrowhead]* designates the ankyrin-binding site in β-spectrin), which in turn binds to the cytoplasmic domain of band 3 *(3)*, and by linkage of protein 4.1 to glycophorin C (GPC). The known protein dysfunctions in HE and HPP include (1) defects of the SpD head region because of a mutation of either α- or β-spectrin, causing impaired assembly of SpD into tetramers, and (2) defects of proteins of the junctional complex such as a qualitative or quantitative defect of protein 4.1R or GPC. *SP*, Spectrin.

mutant spectrin. Because the elliptocytogenic α-spectrin mutants are often unstable, the combination of the two defects leads to spectrin deficiency in the cells. Other HPP patients are homozygous or doubly heterozygous for one or two elliptocytogenic spectrin mutations, respectively. In such cases, the spectrin deficiency may be a consequence of spectrin instability that reduces the amount of spectrin available for membrane assembly. Furthermore, in RBCs containing a high fraction of unassembled dimeric spectrin, the spectrin deficiency may in part be related to the stoichiometric ratio of one ankyrin copy per one spectrin tetramer (i.e., two spectrin heterodimers). Consequently, only approximately one-half of spectrin heterodimers succeed in attaching to the ankyrin-binding sites. The phenotype of HPP, characterized by the presence of fragments and elliptocytes, together with evidence of RBC surface area deficiency (as reflected by the presence of microspherocytes on the peripheral blood film), suggests that the membrane dysfunction involves both vertical interactions (a consequence of spectrin deficiency) and horizontal interactions involving the elliptocytogenic spectrin mutation.

The RBC lesion in protein 4.1R deficiency shows similarities in regard to cell shape and membrane stability to the elliptocytogenic mutations of spectrin, suggesting that the deficiency principally affects the spectrin-actin contact (see Fig. 46.5) rather than the skeleton attachment to GPC via protein 4.1R (a vertical interaction).

The molecular basis of elliptocytosis and the mechanical instability of GPC-deficient RBCs are not fully understood. However, recent studies suggest that the deficiency of GPC is not directly responsible for the altered mechanical properties. Instead, the mechanical instability appears to be related to a concomitant partial deficiency of protein 4.1R, as evidenced by a full correction of membrane instability by introduction into the cells of protein 4.1R or its spectrin-binding peptide, which facilitates the contact of β-spectrin to actin. The superimposed deficiency of protein 4.1R is likely to be related to the fact that GPC serves as an attachment site for protein 4.1R to the membrane, recruiting protein 4.1R to the RBC membrane. The effects of these defects on the mechanical stability of GPC-deficient cells appear to be relatively minor because GPC-deficient patients have no detectable hemolytic anemia and the mechanical properties of the RBCs are normal when tested by micropipette aspiration.

Inheritance

In most patients, HE is inherited as an autosomal dominant disorder. The clinical severity is highly variable among different kindred (reflecting heterogeneous molecular lesions) and, to a lesser extent, within a given kindred, presumably because of other genetic or acquired defects that modify disease expression. Occasionally HE is inherited as an autosomal recessive condition from an asymptomatic parent who carries the same molecular defect of spectrin as the HE offspring. In one kindred with a submicroscopic chromosome X deletion, inheritance was X-linked.

The inheritance of the related disorder HPP is autosomal recessive: one of the parents carries the α-spectrin mutation and either is asymptomatic or has mild HE, whereas the other parent is fully asymptomatic and has no abnormalities detectable by current biochemical approaches. However, several HPP patients have recently been studied who were doubly heterozygous for two α-spectrin mutations; in the heterozygous parents, these mutations were either silent or expressed as mild HE.

Clinical Manifestations

In view of the striking molecular heterogeneity of common HE, it is not surprising that the clinical spectrum of this disorder is variable, ranging from an asymptomatic trait without hemolysis to a life-threatening hemolytic anemia.

Mild Hereditary Elliptocytosis and Asymptomatic Carrier State

In most of these patients, HE is found accidentally during the evaluation of the peripheral blood film. Although some HE patients have a mild compensated hemolytic anemia, others do not have any evidence of hemolysis, their RBC survival is normal, and the peripheral blood film may reveal only modest (≥15%) elliptocytosis. The molecular basis of mild HE is heterogeneous, and the reported molecular defects include both α- and β-spectrin mutations, partial deficiency of the 4.1R protein, and the absence of GPC. Some individuals carrying the spectrin mutation are completely asymptomatic, including normal RBC morphologic features; this is often the case in one of the parents of a patient with HPP.

Hereditary Elliptocytosis With Sporadic Hemolysis

Worsening of hemolysis together with the appearance of poikilocytes on the peripheral blood film has been reported in patients with hypersplenism, infections, or vitamin B_{12} deficiency, as well as in those with microangiopathic hemolysis such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura. In the latter two conditions, worsening hemolysis can be caused by microcirculatory damage superimposed on the underlying mechanical instability of the RBCs.

Hereditary Elliptocytosis With Neonatal Poikilocytosis

Neonatal offspring of parents with mild HE present with symptomatic hemolytic anemia and a marked poikilocytosis. During the first year of life, the hemolysis and poikilocytosis abate, and the clinical picture transforms into that of mild HE. Such patients typically carry one mutant α-spectrin allele. The severity of the molecular defect, in terms of the percentage of spectrin dimers and the amount of mutant spectrin in the cells, is the same in the neonatal period as it is later in life. The worsening of hemolysis in the neonatal period has been attributed to the presence of fetal hemoglobin, which binds poorly to 2,3-diphosphoglycerate (2,3-DPG, also known as 2,3-bisphosphoglycerate or 2,3-BPG). The ensuing elevation of free 2,3-DPG levels has a marked destabilizing effect on the spectrin–protein 4.1R–actin interaction, thereby further destabilizing the membrane skeleton.

Hereditary Elliptocytosis With Chronic Hemolysis

Patients with HE with chronic hemolysis present with moderate to severe hemolytic anemia with elliptocytes and poikilocytes on peripheral blood film; some require splenectomy. In some of the kindred, the hemolytic HE has been transmitted through several generations. In some kindred, not all of the HE patients have chronic hemolysis; some have a mild hemolysis only, presumably because of another genetic factor modifying the disease expression.

Homozygous and Compound Heterozygous Hereditary Elliptocytosis

Several HE individuals have been described who were apparent homozygotes for the HE gene. These individuals were found to be either homozygotes or compound (double) heterozygotes for one or two α- or β-spectrin mutations. The clinical severity is variable, from a relatively mild hemolytic anemia to a severe, life-threatening disease, depending on the severity of the underlying molecular defect, and in some cases is indistinguishable from HPP.

Hereditary Pyropoikilocytosis

It is now established that HPP represents a subtype of common HE, as evidenced by the coexistence of both HE and HPP in the same family and by the presence of the same molecular defect of spectrin. Unlike HE patients carrying the spectrin mutation, the RBCs of HPP patients are also partially deficient in spectrin. Typically, one parent of the HPP offspring carries an α-spectrin mutation, whereas the other parent is fully asymptomatic and has no detectable biochemical abnormality. In many such patients, the asymptomatic parent carries a silent "thalassemia-like" defect of spectrin synthesis, enhancing the relative expression of the spectrin mutant and leading to a superimposed spectrin deficiency in the HPP offspring. Subsequent studies of the original HPP kindred revealed that defective spectrin synthesis from the null allele was caused by a splicing mutation of the α-spectrin gene. Some HPP patients inherited two α-spectrin mutations; either their parents were hematologically normal or one had mild HE. In these HPP patients, spectrin deficiency may be related to the instability of the mutant spectrin. The thermal instability of spectrin originally reported as diagnostic of HPP is not unique for this disorder; it is also found in HE patients carrying this α-spectrin mutation and in the homozygous and in the heterozygous states. HPP is seen predominantly in Black patients, but it has also been diagnosed in Arabs and Whites.

Molecular Determinants of Clinical Severity

The severity of hemolysis in common HE often varies not only among different kindred but within a given family as well. The two principal determinants of severity of hemolysis are the spectrin content of the cells and the percentage of dimeric spectrin in the crude spectrin extract. The fraction of dimeric spectrin in such extracts in turn depends on several factors. The first of them is the degree of dysfunction of the mutant spectrin. Typically, mutations that are either within or near the combined αβ triple-helical repetitive segment representing the spectrin heterodimer self-association site produce a more severe clinical phenotype and a more severe defect of spectrin function than those seen with point mutations in the more distant triple-helical repeats. Second, the percentage of the dimeric spectrin depends on the fraction of the mutant spectrin in the cells, which in turn is determined by the gene dose (e.g., simple heterozygote versus homozygote or double heterozygote) or the presence of other genetic defects such as the presence, in trans, of a defect leading to a reduced α-spectrin synthesis in some patients with HPP.

The low-expression α-spectrin allele α^{LELY} is the best-characterized abnormality affecting spectrin content and clinical severity. Initially, a polymorphism of the αV domain, $\alpha^{V/41}$ was identified in HE patients who, when they inherited $\alpha^{V/41}$ in trans, had more severe HE than expected. Subsequently, an amino acid substitution of exon 46, Leu1857Val, and partial skipping of exon 46, linked to the $\alpha^{V/41}$ polymorphism, were identified as the characteristics of the α^{LELY} allele. These abnormalities are located within the site at which spectrin monomers assemble into heterodimers (the spectrin heterodimer nucleation site). In vitro studies suggest that the inability of α-spectrin chains to assemble into the mature membrane skeleton is because of a combination of decreased αβ dimer-binding affinity and increased proteolytic cleavage of the mutant α-spectrin chains. The presence of α^{LELY} in trans diminishes the propensity of the otherwise normal allele to associate with the corresponding β-chain, favoring the attachment of the elliptocytogenic α-spectrin allele. Conversely, the coexistence of the α-spectrin mutation in cis and the mutation involving the α-spectrin nucleation site diminishes the propensity of the mutant allele to be incorporated into the spectrin heterodimer, thereby ameliorating the clinical severity of this mutation. The α^{LELY} allele is clinically silent by itself, even when inherited in the homozygous state, probably because α-spectrin is normally synthesized in threefold to fourfold excess.

Laboratory Manifestations

Blood Film and Laboratory Evidence of Hemolysis

A careful blood smear evaluation is essential for the diagnosis of HE and for the classification of the disorder into the three major subtypes outlined previously. In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is characteristically minimal or absent, with the exception of spherocytic elliptocytosis, in which the presence of round "fat" ovalocytes is associated with accelerated RBC destruction. In patients with hemolytic forms of common HE, poikilocytosis is characteristically found on the blood film. In severe forms of HE, particularly in homozygous HE, many RBCs circulate as cell fragments, producing a marked decrease in MCV. The finding of RBC fragments together with a striking microspherocytosis and often only occasional elliptocytes is characteristic of HPP (Fig. 46.6).

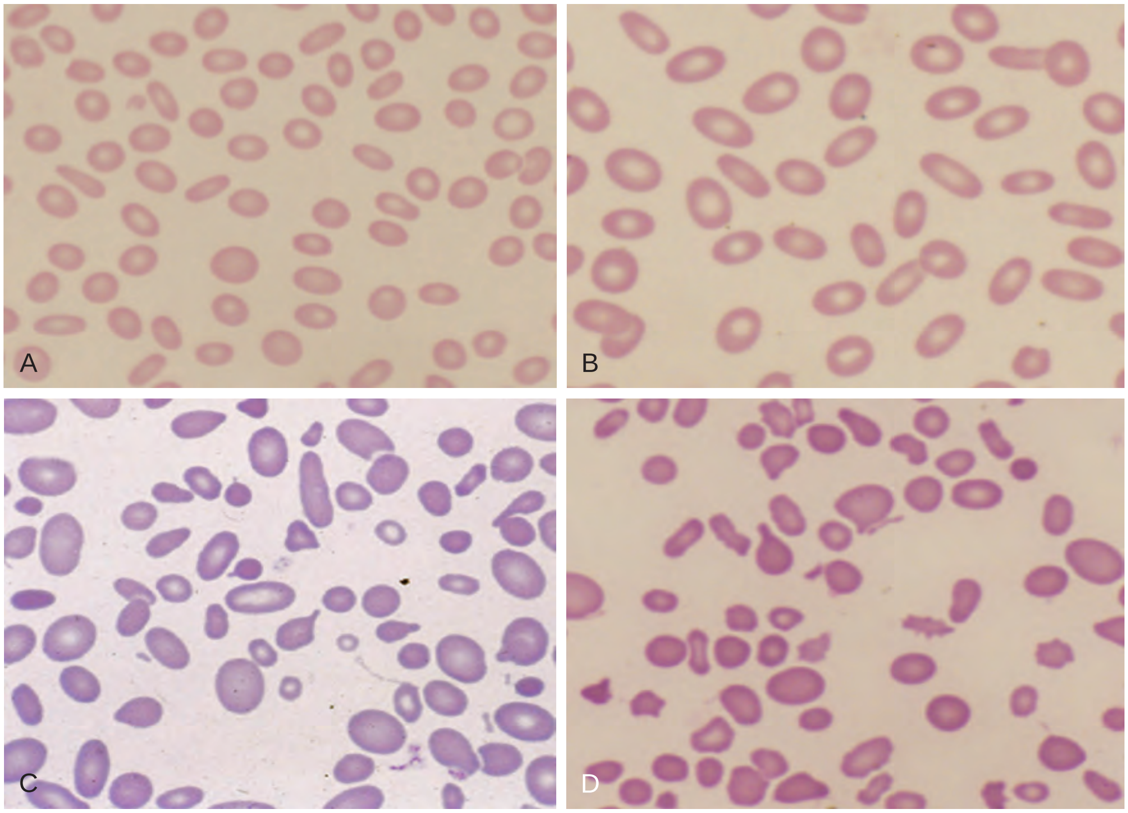

Figure 46.6 BLOOD FILMS OF PATIENTS WITH VARIOUS FORMS OF HEREDITARY ELLIPTOCYTOSIS (HE). (A) Simple heterozygote with mild common HE. Note the predominant elliptocytosis with some rod-shaped cells *(arrow)* and virtual absence of poikilocytes. (B) Simple heterozygote with severe common hemolytic elliptocytosis. Note the numerous small fragments and poikilocytes. (C) "Homozygous" common HE because of doubly heterozygous state for two mutant α-spectrins. Both parents have mild HE. Note the many elliptocytes, spherocytes, as well as numerous fragments and poikilocytes. (D) Hereditary pyropoikilocytosis. The patient is a double heterozygote for a structural α-spectrin mutant and a presumed α-spectrin synthetic defect. Note the prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only a few elliptocytes are present. Some poikilocytes are in the process of budding.

Osmotic and Thermal Fragility

Osmotic fragility is increased in HPP, in spherocytic elliptocytosis, and in HE patients with poikilocytosis apparent on the peripheral blood film. In patients with a mild common HE without poikilocytosis on the peripheral blood film, osmotic fragility is normal.

Thermal instability of RBCs was originally reported as a characteristic feature of HPP. It reflects thermal instability of the mutant spectrin: In normal RBCs, spectrin is denatured and RBCs fragment at 50°C. HPP RBCs fragment and their spectrin denatures at 41°C. However, the diagnostic value of this test is limited because the thermal instability of RBCs is also noted in HE RBCs containing mutant spectrin. In contrast, an occasional patient with otherwise typical HPP may have normal thermal stability of RBCs and spectrin. RBCs in common HE have unstable membranes and membrane skeletons when subjected to shear stress.

Electrophoretic Separation of Solubilized Membrane Proteins

In HE and HPP, SDS-PAGE can reveal proteins of abnormal mobility, and the origin of which can be subsequently identified by Western blotting (e.g., truncated α- or β-spectrins in HE and HPP, or elongated or truncated forms of the 4.1R protein, and a partial or, rarely, complete deficiency of the 4.1R protein in HE). In HPP, SDS-PAGE reveals a partial deficiency of spectrin, as indicated by a decreased spectrin/band 3 ratio. Spectrin deficiency, in conjunction with an elliptocytogenic spectrin mutation affecting the spectrin heterodimer contact, is invariably found in cases of HPP.

Nondenaturing Gel Electrophoresis of Low-Ionic-Strength Spectrin Extract

Analysis of the ratio of tetrameric and dimeric spectrin in the low-ionic-strength extracts reveals the most common functional abnormality in HE (i.e., weakened self-association of spectrin heterodimers into tetramers). Because the spectrin dimer-tetramer interconversion has a high activation energy, it is kinetically immobilized at near 0°C. Consequently, the percentage of spectrin dimers and tetramers in the 0°C crude spectrin extract reflects the relative distribution of these species in the RBC membrane in situ. Mutations of α- or α-spectrin residing within or near the αβ-spectrin heterodimer self-association site invariably lead to an increase in the fraction of dimeric spectrin in the crude 0°C spectrin extract.

Tryptic Peptide Mapping of Spectrin and the Detection of the Underlying DNA Defect

Tryptic digestion of spectrin followed by electrophoretic separation gives rise to highly reproducible tryptic peptide patterns. Among these peptides, the 80-kDa αI domain peptide representing the self-association site of the normal α-spectrin is among the most prominent. Nearly all α- or β-spectrin mutations reported are associated with a formation of tryptic peptides of abnormal size and mobility that are generated from the normal 80-kDa αI domain peptide. The cleavage sites of the most common abnormal tryptic peptides are found in the third helix of a given triple-helical repetitive segment. The reported mutations reside in the vicinity of these cleavage sites either in the same helix or, less commonly, in helix 1 or 2 of a given repetitive segment. Consequently, tryptic peptide mapping remains a powerful tool with which to map the site of the underlying spectrin mutation, which can be subsequently defined by polymerase chain reaction amplification and sequencing of the respective region of the genomic DNA or complementary DNA (cDNA).

Differential Diagnosis

Various acquired and inherited conditions can be associated with elliptocytosis and poikilocytosis, including iron deficiency, thalassemias, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndromes, and pyruvate kinase deficiency. The percentage of elliptocytes in these conditions is seldom greater than 60%. However, this is not diagnostically useful because some HE patients can have a relatively low percentage of elliptocytes. In normal patients, the percentage of elliptocytes is not greater than 5%, although in earlier reports it was listed as high as 15%. Previous diagnostic criteria of HE, based on the percentage of elliptocytes, such as 25%, 33%, or 40%, and their axial ratio, do not appear useful. The most reliable differentiation of HE from the other conditions mentioned is based on a positive family history rather than on the percentage of elliptocytes.

Therapy and Prognosis

As in the case of HS, RBCs from patients with more severe forms of HE are retained by the spleen, producing a marked engorgement of splenic pulp. Consequently, patients with symptomatic hemolysis benefit from splenectomy. This procedure is virtually never indicated in heterozygotes with autosomal dominant HE because most do not have clinically significant hemolytic anemia. If hemolysis is still active after splenectomy, folate should be administered daily. Recommendations for antibiotic prophylaxis, immunizations, and monitoring for intercurrent illnesses are similar to those noted earlier for HS patients before and after splenectomy. Serial interval ultrasonographic investigations to detect gallstones should be performed in patients with significant hemolysis.

Spherocytic Elliptocytosis

Spherocytic elliptocytosis, which shares features of HS and HE, has been designated spherocytic HE, HE with spherocytosis, or hereditary hemolytic ovalocytosis. The diagnosis is based on the simultaneous presence of elliptical RBCs and spherocytes or “fat,” round sphero-ovalocytes in the peripheral blood film. In contrast to common HE, cells of other shapes, such as rod-shaped cells, poikilocytes, and fragments, are absent. Importantly, hemolysis, despite relatively mild alterations in RBC morphologic features, and increased osmotic fragility are the main diagnostic features distinguishing this disorder from common HE.

The molecular basis of spherocytic HE is unknown. However, patients with mutations, particularly truncations at the C-terminal of β-spectrin, have many of the clinical features of spherocytic HE and probably represent an example of this disorder. Patients who lack GPC have rounded, smooth elliptocytes and could be classified as having a mild, recessively inherited variant of spherocytic HE. Finally, some patients with recessively inherited defects of protein 4.2 can display some features of spherocytic HE, particularly mild ovalostomatocytosis.

Southeast Asian Ovalocytosis

SAO is characterized by the presence of oval RBCs, many containing one or two transverse ridges or a longitudinal slit. The condition is widespread in certain ethnic groups of Malaysia, Papua New Guinea, the Philippines, and Indonesia. Numerous functional abnormalities of ovalocytes have been reported, including increased RBC rigidity, decreased osmotic fragility, increased thermal stability, resistance to shape change by echinocytogenic agents, and a reduced expression of many RBC antigens. A remarkable feature of ovalocytes is their resistance to in vitro invasion by several strains of malaria parasites, including *P. falciparum* and *Plasmodium knowlesi*. In areas of endemic malaria, SAO individuals have reduced numbers of intracellular parasites in vivo, with decreased prevalence and disease severity of malaria in SAO patients compared with controls.

SAO individuals are heterozygotes for two band 3 gene mutations in cis: the deletion of nine codons encoding amino acids 400 through 408 from the boundary of the cytoplasmic and membrane domains of band 3, and the 56 Lys to Glu substitution. The 56 Lys to Glu substitution represents an asymptomatic polymorphism known as band 3 Memphis. The SAO phenotype is associated with a tighter binding of band 3 to ankyrin, increased tyrosine phosphorylation of the band 3 protein, inability to transport sulfate anions, and a markedly restricted lateral and rotational mobility of band 3 protein in the membrane.

Laboratory Manifestations

The finding of 30% or greater of oval RBCs on the peripheral blood film, some containing a central slit or a transverse ridge, in the context of a notable absence of clinical and laboratory evidence of hemolysis in a patient from the ethnic groups noted earlier is highly suggestive of the diagnosis. A useful screening test is the demonstration of the resistance of ovalocytes or their ghosts to changes in shape produced by treatments that produce spiculation in normal cells, such as metabolic depletion or exposure of ghosts to salt solutions. In contrast to normal RBCs, which form spicules in response to such stimuli, SAO RBCs or ghosts do not change shape after these treatments. The mechanism of this resistance to changes in shape is not clear, and it may reflect the high rigidity of the RBC membrane.

Because the underlying cause of SAO is the deletion of 27 bases from the band 3 gene, isolation of genomic DNA or reticulocyte cDNA with subsequent amplification of the deletion-containing region appears to be the most specific test for establishing the diagnosis of SAO. A single, severely affected homozygous SAO individual who was transfusion dependent has been described.

Molecular Basis of Southeast Asian Ovalocytosis Membrane Rigidity and Malaria Resistance

The RBCs of SAO are unique among axially deformed cells in that they are rigid and hyperstable rather than unstable. The SAO mutation is the first example of a defect of an integral membrane protein leading to RBC membrane rigidity, an observation previously attributed to properties of the membrane skeleton. The basis of the increased rigidity is unclear.

The molecular basis of malaria resistance of SAO RBCs is likely related to altered properties of the band 3 protein, which serves as one of the malaria receptors, as evidenced by the inhibition of in vitro invasion by band 3-containing liposomes. In normal RBCs, the invasion process is associated with a marked membrane remodeling that involves the redistribution of intramembrane particles that contain band 3 protein. Such particles cluster at the site of parasite invasion, forming a ring around the orifice through which the parasite enters the cell. The invaginated RBC membrane, which surrounds the invading parasite, is free of intramembrane particles. The reduced lateral mobility of band 3 protein in SAO RBCs may preclude band 3 receptor clustering, thereby preventing the attachment of the parasites to the cells. Decreased exchange of anions across the RBC membrane has also been proposed to contribute to the resistance of ovalocytes to malaria invasion. In addition, SAO

RBCs consume ATP at a higher rate than normal cells, and the partial depletion of ATP levels in ovalocytes has been suggested to account, at least in part, for the resistance of these cells to malaria invasion in vitro.

Acanthocytosis and Related Disorders

Acanthocytes (from the Greek *acantha*, "thorn") or spur cells are RBCs with prominent thorn-like surface protrusions that vary in width, length, and surface distribution. Spur cells must be distinguished from echinocytes (Greek *echinos*, "sea urchin") or burr cells, characterized by multiple small projections that are uniformly distributed throughout the cell surface (Fig. 46.7). Acanthocytes should also be distinguished from keratocytes ("horn" red cells) that have few massive protuberances.

Acanthocytosis was first described in cases of abetalipoproteinemia and subsequently in severe liver disease, the chorea-acanthocytosis syndrome, the McLeod blood group phenotype, and other conditions. The molecular mechanisms leading to acanthocytosis in abetalipoproteinemia and severe liver disease have been extensively studied and have been attributed to changes in composition of membrane lipids and their altered distribution between the two hemileaflets of the lipid bilayer.

Spur Cell Hemolytic Anemia of Severe Liver Disease

Spur cell hemolytic anemia is an uncommon ominous complication of severe liver disease that is manifested by rapidly progressive hemolytic anemia and acanthocytes on the peripheral blood smear.

Pathobiology

The human RBC membrane contains nearly equal amounts of free (unesterified) cholesterol and phospholipids. The free cholesterol in the plasma readily equilibrates with the RBC membrane cholesterol pool. This is in contrast to esterified cholesterol, which cannot be transferred from plasma into the RBC membrane. The plasma of patients with severe liver disease contains abnormal lipoproteins that have a high free cholesterol/phospholipid ratio. The excess free cholesterol readily partitions into the RBC membrane, leading to a marked increase in free cholesterol in the cells. Consequently, normal cells can develop a spur cell shape after their transfusion into a patient with severe liver disease or after incubation with the liver disease patient's plasma or cholesterol-enriched liposomes.

Spur cell formation involves two steps. The first step is evident in RBCs of splenectomized patients with spur cell hemolytic anemia: RBCs have an expanded surface area with irregular contour and targeting, reflecting the accumulation of free cholesterol in the membrane (Fig. 46.8). This extracholesterol accumulates preferentially in the outer bilayer leaflet, as suggested by findings of increased accessibility of cholesterol to cholesterol oxidase and a selective decrease in lipid fluidity of the outer hemileaflet of the lipid bilayer.

The second step in acanthocyte formation involves RBC remodeling by the spleen. As a result, RBCs become spheroidal, and the surface projections are considerably longer and more irregular. The end result of these processes is poorly deformable RBCs with long bizarre projections that are readily trapped in the spleen, which is often markedly enlarged because of passive congestion as a result of underlying portal hypertension. Cholesterol also alters membrane permeability and interacts with several membrane skeletal proteins, but the role of these changes in spur cell lesions is unclear.

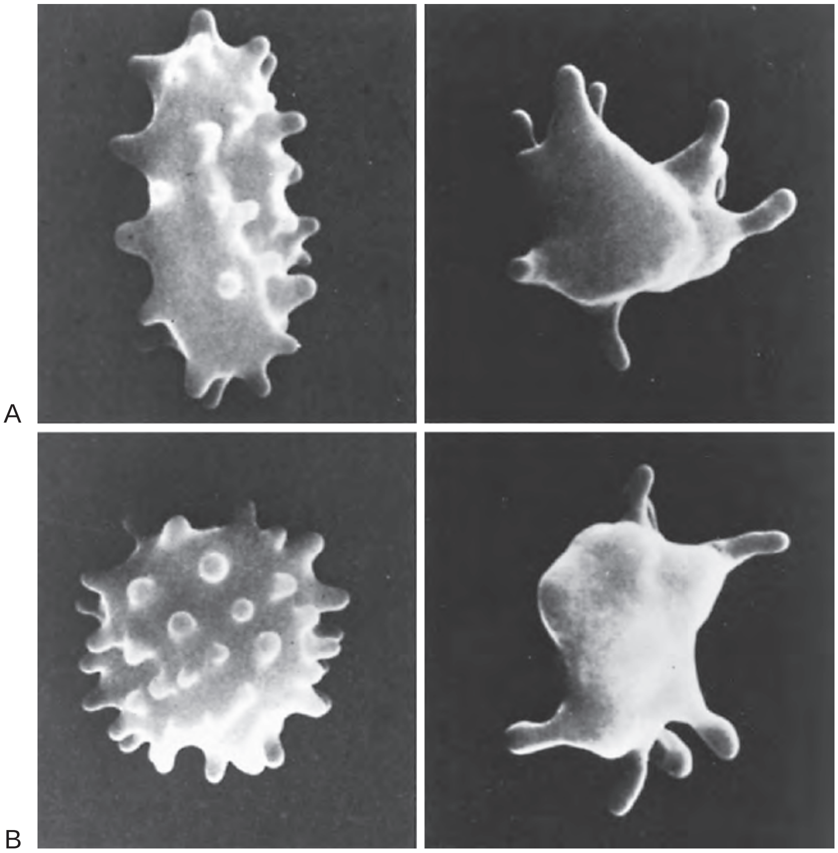

Figure 46.7 MORPHOLOGIC DIFFERENCES BETWEEN ACANTHOCYTES (A) AND ECHINOCYTES (B) AS DEMONSTRATED BY SCANNING ELECTRON MICROSCOPY. *(Modified from Bessis M. Red cell shapes: an illustrated classification and its rationale. In: Bessis M, Weed RI, Leblond PF, eds. Red Cell Shape Physiology, Pathology, Ultrastructure. New York: Springer-Verlag; 1973.)*

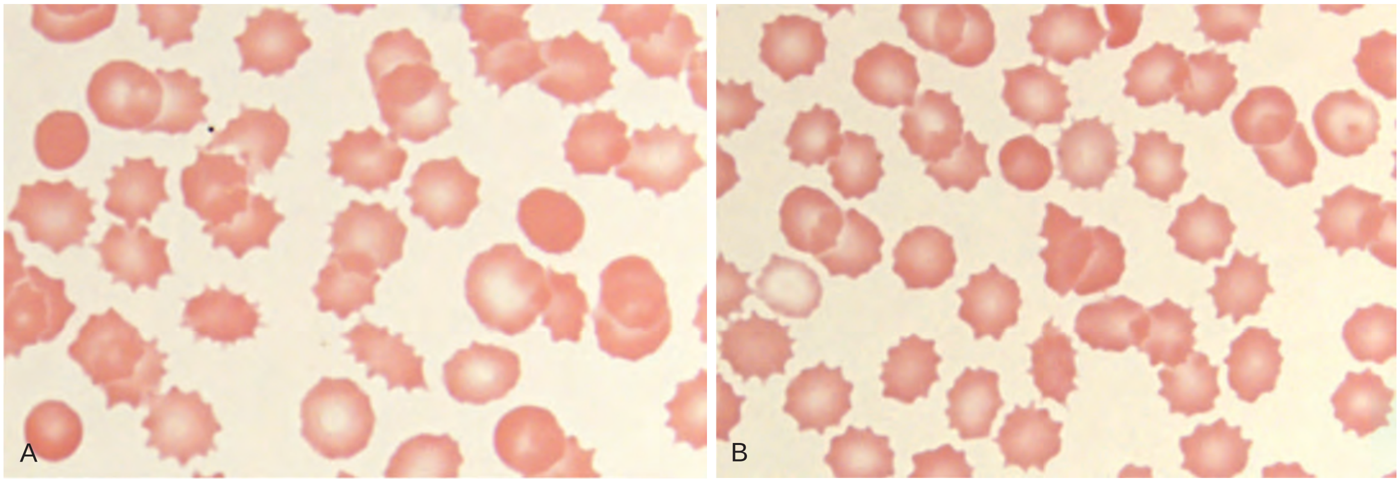

Figure 46.8 BLOOD FILM OF A PATIENT WITH LIVER CIRRHOSIS AND SPUR CELL ANEMIA. Erythrocytes have an expanded surface area with irregular contour and targeting, reflecting the accumulation of free cholesterol in the membrane, preferentially in the outer bilayer leaflet. Splenic remodeling leads to increasing spheroidicity with longer and more irregular surface projections.

Clinical Manifestations

Most patients with chronic liver disease have a mild to moderate anemia related to gastrointestinal blood loss, iron and folic acid deficiencies, or hemodilution or as a direct effect of alcohol on RBC precursors. Peripheral blood smears from these patients often reveal target cells that are particularly prominent in obstructive jaundice.

In some patients, particularly those with end-stage liver disease, anemia rapidly worsens and spur cells appear in high percentage in the peripheral blood. This is accompanied by worsening jaundice, rapid deterioration of liver function, hepatic encephalopathy, and hemorrhagic diatheses. A similar clinical syndrome has been described in patients with advanced metastatic liver disease, cardiac cirrhosis, Wilson disease, fulminant hepatitis, and infantile cholestatic liver disease. The development of spur cell hemolytic anemia is an ominous sign in most patients, predicting a survival seldom exceeding weeks to months. In theory, splenectomy could provide a marked improvement because the spleen is the major sequestration site of nondeformable acanthocytes; in reality, splenectomy is seldom considered because of the severity of the underlying liver disease.

Abetalipoproteinemia

Bassen and Kornzweig first described an association of acanthocytosis with atypical retinitis pigmentosa, progressive ataxic neurologic disease, and a “celiac disease” later attributed to fat malabsorption. Subsequently, several investigators reported a congenital absence of β-lipoprotein, accounting for the diverse manifestations of the disorder.

Pathobiology

Abetalipoproteinemia is an autosomal recessive disorder found in people of diverse ethnic backgrounds. The primary molecular defect involves a congenital absence of β-apolipoprotein in plasma. The B apoproteins (B100 and B48) are generated by alternate transcription of a single gene residing on the short arm of chromosome 2. Their deficiency is secondary to the defective cellular secretion of the apoprotein by liver cells, caused either by aberrant posttranslational processing or by defective aposecretion. In some patients, this is because of qualitative or quantitative defects in the microsomal triglyceride transfer protein, which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces. Microsomal triglyceride transfer protein is the only tissue-specific component, other than apolipoprotein B, required for the secretion of apolipoprotein B-containing lipoproteins. As a result, apoprotein B is absent in plasma, as are the individual lipoprotein fractions that contain this apoprotein. These lipoprotein fractions include chylomicrons and very-low-density lipoproteins that transport triglycerides, as well as the low-density lipoproteins that are products of very-low-density lipoproteins and transport cholesterol. Consequently, preformed triglycerides are not transported from the intestinal mucosa, and they are nearly absent in the plasma. Plasma cholesterol and phospholipids are markedly reduced, with a relative increase in sphingomyelin at the expense of lecithin.

As is the case in acanthocytosis of liver disease, the acanthocytic lesion is acquired from the plasma. Erythrocyte precursors are of normal shape, and the acanthocytic lesion develops as the cells mature and age in the circulation. Normal cells acquire this shape when transfused into the recipient.

The most striking abnormality of RBC membrane lipids involves a net increase in sphingomyelin. Because plasma lipids readily exchange with the lipids of the RBC membrane, it is likely that this change simply mirrors the alterations in plasma lipid composition. In contrast to RBCs in spur cell anemia of severe liver disease, the content of membrane cholesterol is normal or only slightly increased.

The role of membrane lipids in the acanthocyte shape transformation was first established by findings of restoration of biconcave shape after extraction of lipids from the cell membrane by detergents. The molecular basis of the acanthocytic shape is unknown, but several indirect observations suggest that it is related to an increase of the surface area of the outer hemileaflet of the lipid bilayer relative to the inner leaflet. Several other abnormalities have been noted in abetalipoproteinemia, including a decrease in plasma lecithin-cholesterol transferase activity and an increased susceptibility of membrane and plasma lipids to oxidation as a result of malabsorption-induced deficiency of vitamin E. The contributions of these abnormalities to the acanthocyte red cell lesions are unknown.

Clinical Manifestations

This autosomal recessive disease can become evident in the first few months of life, manifested by fat malabsorption with normal absorption of other nutrients. Intestinal biopsy is diagnostic, revealing engorgement of mucosal cells with lipid droplets. Other features include retinitis pigmentosa and a progressive ataxia with intention tremors that usually develops at 5 to 10 years of age, progressing to death in the second or third decade of life. The hematologic manifestations are mild and include mild normocytic anemia with acanthocytosis (50% to 90%) and normal or slightly elevated reticulocyte counts. Occasional patients can have more severe anemia resulting from the nutritional deficiencies (iron and folate) that accompany fat malabsorption. The treatment includes dietary restriction of triglycerides and supplementation with the lipid-soluble vitamins A, K, D, and E. Vitamin E can stabilize or even improve both the retinal and neuromuscular abnormalities.

Autosomal recessive abetalipoproteinemia should be distinguished from the homozygous form of familial hypobetalipoproteinemia. Although the clinical presentation of both disorders is similar, the latter disorder is milder, and the parents have occasional acanthocytes on the peripheral blood film, and their plasma low-density lipoprotein levels are decreased. The molecular lesions in familial hypobetalipoproteinemia involve a variety of apoprotein B gene mutations, leading to aberrant apoprotein B gene transcription or translation.

Varying degrees of acanthocytosis without anemia have also been described with isolated deficiency of apoprotein B100.

Neuroacanthocytosis Syndromes

The neuroacanthocytosis syndromes are a group of degenerative neurologic disorders with phenotypic and genetic heterogeneity that share the feature of acanthocytes on peripheral blood smear. These disorders include chorea-acanthocytosis, the X-linked McLeod syndrome (see McLeod Phenotype), and several other neurodegenerative diseases, including Huntington disease-like 2 caused by mutations in junctophilin-3 and pantothenate kinase-associated neurodegeneration (formerly known as Hallervorden-Spatz syndrome and its allelic variant syndrome—hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, pallidal degeneration [HARP]) caused by mutations in pantothenate kinase 2.

Chorea-acanthocytosis syndrome is an autosomal recessive syndrome of adult onset that is manifest by multiple neurologic abnormalities, including limb chorea, progressive orofacial dyskinesia with tics, tongue-biting neurogenic muscle hypotonia, and atrophy. The hematologic manifestations are minimal and include a variable percentage of acanthocytes on the peripheral blood film without anemia and normal or only slightly decreased RBC survival. The mechanism of acanthocytosis in this syndrome is unknown. Studies of plasma and RBC membrane lipids have revealed a high content of unsaturated fatty acids, presumably accounting for reduced RBC membrane fluidity. Additional abnormalities of uncertain significance include an uneven distribution of intramembrane particles, impaired phosphorylation of the erythrocyte actin-bundling protein dematin, abnormal accumulation of transglutaminase products, and altered function and structure of band 3.

Mutations have been identified in the chorein gene (also known as *CHAC* or *VPS13A*—vacuolar protein sorting 13 homolog A) in many affected patients. Chorein does not belong to any known human gene family, and computer searches have not identified any known structural motifs or domains. The function of the chorein gene product remains unknown in either erythrocytes or the brain. In yeast, a chorein homologue is involved in protein sorting and transport and in the regulation of levels of phosphatidylinositol-4-phosphate in cell membranes.

McLeod Phenotype

The McLeod syndrome is characterized by a mild compensated hemolytic anemia with a variable percentage of acanthocytes on the peripheral blood film and, in some patients, late-onset myopathy or chorea. The McLeod blood group phenotype is an X-linked anomaly of the Kell blood group system in which RBCs, white blood cells, or both react poorly with Kell antisera. The affected cells lack Kx, the product of the *XK* gene, which appears to be a membrane precursor of the Kell antigens. The *XK* gene encodes a novel 444-amino acid integral membrane transporter. In most patients, pathogenic nonsense or deletion mutations lead to absent or shortened XK protein that lacks the Kell protein binding site. Male hemizygotes who lack Kx have variable acanthocytosis (8% to 85%) and mild, compensated hemolysis. Because of the RBC mosaicism predicted by the Lyon hypothesis of X chromosome inactivation, female heterozygote carriers can have occasional acanthocytes on the peripheral blood film. Lyonized women with more severe symptoms have been described. Diagnosis may be challenging. CK levels are almost always elevated. In affected males, erythrocytes demonstrate absent Kx antigen and reduced Kell antigens. Because of the susceptibility to alloimmunization, it is important to diagnose affected patients because if they are transfused, they can develop antibodies compatible only with McLeod red cells.

The McLeod syndrome has been reported in association with chronic granulomatous disease of childhood, retinitis pigmentosa, and Duchenne muscular dystrophy. This association is caused by the close proximity of the genetic loci for these disorders in the p21 region of the X chromosome (Xp21), suggesting the occurrence of various manifestations because of contiguous gene syndromes. This may explain the occasional findings of either echinocytes or stomatocytes in Duchenne dystrophy or a choreiform disorder in some patients with the McLeod phenotype.

The Kell antigen consists of two protein components: a 37-kDa protein that carries the Kx antigen, a precursor molecule necessary for the Kell antigen expression, and a 93-kDa protein that carries the Kell blood group antigen. RBCs with the McLeod phenotype have no detectable Kx antigen, and they have a marked deficiency of the 93-kDa protein that carries the Kell antigen. McLeod RBCs should be distinguished from Kell null (K_0) RBCs, which have a normal shape. In K_0 cells, only the Kell antigen carrying the 93-kDa glycoprotein is absent, whereas these cells have twice the amount of the Kx antigen. As in the other acanthocytic disorders, the surface projections of acanthocytes may be related to the asymmetry of the surface area of the two lipid bilayer hemileaflets, as indicated by correction of the acanthocytosis by agents that expand the inner lipid layer, as well as the finding of an increased rate of exchange of phosphatidylcholine (localized preferentially in the outer lipid hemileaflet) with an exogenous source.

Acanthocytosis in Other Conditions

Acanthocytes have also been noted in malnourished patients, including those with anorexia nervosa and cystic fibrosis. In these patients, RBC shape normalizes after restoration of the nutritional status. Likewise, a small number of cells with long spicules resembling acanthocytes are found in patients with hypothyroidism, after splenectomy, and with myelodysplasia.

Differentiation of Acanthocytes From Other Spiculated Red Blood Cells

Echinocytes (Burr Cells)

In contrast to acanthocytes, echinocytes, also called burr cells, have rather uniform surface projections. Although early echinocytic forms have a regularly scalloped cell contour, advanced forms of echinocytes have a spheroidal shape and the surface projections appear as short, narrow spikes (see Fig. 46.8). Although the finding of echinocytes on a peripheral blood film is often an artifact related to blood storage, contact with glass, or an elevated pH, several hemolytic anemias have been reported in association with echinocytosis on peripheral blood films. These conditions include mild hemolytic anemia in long-distance runners and in patients with hypomagnesemia and hypophosphatemia (presumably because of decreased intracellular ATP stores), uremia because of an unknown plasma factor, and pyruvate kinase deficiency.

Inspection of wet blood preparations (but not dried blood films) reveals echinocytosis in most patients with liver disease. In contrast to spur cells in patients with severe liver disease, these echinocytes have a normal cholesterol content, and the molecular abnormality may be related to the binding of abnormal echinocytogenic high-density lipoproteins to the RBC surface.

The mechanisms of echinocytosis in these diverse disorders are likely to be heterogeneous, as suggested by findings that many diverse factors, such as exposure of RBCs to certain drugs, calcium loading, or ATP depletion, can induce the transformation of discocytes to echinocytes in vitro. However, in vitro studies of the discocyte-echinocyte-stomatocyte equilibrium have suggested a possible common denominator. As discussed earlier, the lipid bilayer of normal RBCs is asymmetric in lipid composition: The outer half of the lipid bilayer is relatively enriched in sphingomyelin and phosphatidylcholine, whereas the inner half is preferentially enriched in the negatively charged phosphatidylserine and phosphatidylethanolamine. Agents that preferentially bind to one or another class of these phospholipids dramatically influence RBC shape. Consequently, agents that preferentially accumulate in the outer half of the RBC lipid bilayer, expanding this lipid bilayer, produce an echinocytic shape, presumably by creating an asymmetry between the two surface areas of the two halves of the lipid bilayer. Conversely, agents that asymmetrically expand the inner half of the lipid bilayer, such as chlorpromazine, lead to stomatocytic shape transformation. In the case of echinocytes produced by ATP depletion or calcium loading, the altered phospholipid distribution between the two bilayer hemileaflets may be a consequence of calcium-induced phospholipid scrambling or a decrease in the activity of aminophospholipid translocase, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer leaflet to the inner hemileaflet.

Keratocytes, Bizarre Poikilocytes, and Schistocytes

Mechanical trauma of circulating RBCs has occasionally produced bizarre shapes resembling acanthocytes, such as cells with horny projections (keratocytes). Some acanthocyte-like cells are also seen in splenectomized HE and HS patients. Similar shape changes are seen in heated RBCs, in which spectrin has been damaged by thermal denaturation, suggesting that these cells are bizarre poikilocytes rather than true acanthocytes.

RED BLOOD CELL MEMBRANE DISORDERS MANIFESTED BY TARGET CELL FORMATION

The common feature of target cells is an increase in the ratio of the cell surface area to cell volume. In microcytic RBCs of patients with various forms of thalassemia and hemoglobinopathies, the increased surface to volume ratio, and consequently the target cell shape, reflect at least in part the relative abundance of cell surface area. In liver disease and other disorders discussed subsequently, the target cell formation reflects an absolute expansion of the cell surface area because of a net accumulation of membrane phospholipids and cholesterol.

Liver Disease

The presence of target cells in association with either normal or slightly increased cell volume is characteristically found in patients with obstructive jaundice, including various forms of liver disease associated with intrahepatic cholestasis. These target cells have a normal survival in the peripheral circulation and do not typically account for the anemias often encountered in patients with liver disease.

In these patients, target cell formation is a consequence of a net uptake of both free cholesterol and phospholipids into the RBC membrane from the plasma because of abnormalities in the cholesterol/phospholipid/protein ratios of low-density lipoproteins. Target cells have a decreased osmotic fragility because the excess of membrane surface area leads to an increase in the critical hemolytic volume.

Lecithin-Cholesterol Acyltransferase Deficiency

The lecithin-cholesterol acyltransferase (LCAT) enzyme catalyzes the formation of cholesterol esters in lipoproteins. It circulates in plasma as a complex with components of high-density lipoproteins. LCAT deficiency, caused by mutations in the *LCAT* gene, is a rare autosomal dominant disorder manifested by hyperlipidemia, premature atherosclerosis, corneal opacities, chronic nephritis, proteinuria, mild anemia, and the presence of target cells on the blood film. The anemia is caused by mild hemolysis together with a diminished compensatory erythropoiesis. As in obstructive jaundice, the target cells in LCAT deficiency have a marked increase in both cholesterol and phospholipids. In addition, the membrane phosphatidylcholine is increased at the expense of sphingomyelin and phosphatidylethanolamine. Bone marrow aspiration and biopsy reveal the presence of sea-blue histiocytes. Analysis of plasma lipoproteins reveals multiple abnormalities secondary to the underlying enzyme deficiency. Inherited LCAT deficiency should be distinguished from an acquired deficiency of this enzyme, which is found in patients with severe liver disease.

Stomatocytosis and Related Disorders

Stomatocytes were first described in a girl with dominantly inherited hemolytic anemia. On blood films, her RBCs contained a wide transverse slit or stoma (Fig. 46.9). In a three-dimensional view, these cells have a shape of a cup or a bowl. The slit-like appearance is an artifact that results from folding of the cells during blood smear preparation.

Stomatocytes are seen in a variety of acquired and inherited disorders. The latter are often associated with abnormalities in RBC cation permeability that lead to changes in RBC volume, which can be either increased (hence the designation hydrocytosis or overhydrated stomatocytosis) or decreased (xerocytosis or desiccytosis [dessicate]), or in some cases near normal.

There is no unifying theory to explain this morphologic abnormality. In vitro, stomatocytes can be produced by drugs that preferentially intercalate into the inner half of the asymmetric lipid bilayer, expanding its surface area relative to that of the outer half of the bilayer.

Hereditary Stomatocytosis-Hydrocytosis

Hereditary hydrocytosis designates a heterogeneous group of hereditary hemolytic anemias that are transmitted in an autosomal dominant manner. The disorder is characterized by a moderate to severe hemolytic anemia with 10% to 30% stomatocytes (see Fig. 46.9), an elevated MCV, and a reduced MCHC. Osmotic fragility of RBCs is markedly increased, as some of the swollen RBCs approach their critical hemolytic volume. For unexplained reasons, RBC membrane lipids and consequently membrane surface area are also increased, but this increase in surface area is insufficient to correct the osmotic fragility of the RBCs. RBC deformability is decreased.

The principal cellular lesion involves a marked increase in intracellular sodium and water content with a mild decrease in intracellular potassium as a result of a marked sodium influx into the RBCs. Despite a marked compensatory increase in active transport of sodium (Na) and potassium by the Na^+/K^+-ATPase (which normally maintains the low sodium and high potassium concentrations in the cells) and an ensuing increase in glycolysis, the pump hyperactivity is unable to compensate for the vastly increased sodium leak. Stomatin (also known as band 7.2b), an integral membrane protein, is decreased or absent from the erythrocyte membranes of most affected patients. This deficiency appears to be a maturational loss in the bone marrow and in the circulation, perhaps because of a defect in cellular trafficking. Stomatin gene mutations have not been found in unrelated stomatocytosis patients deficient in this protein.

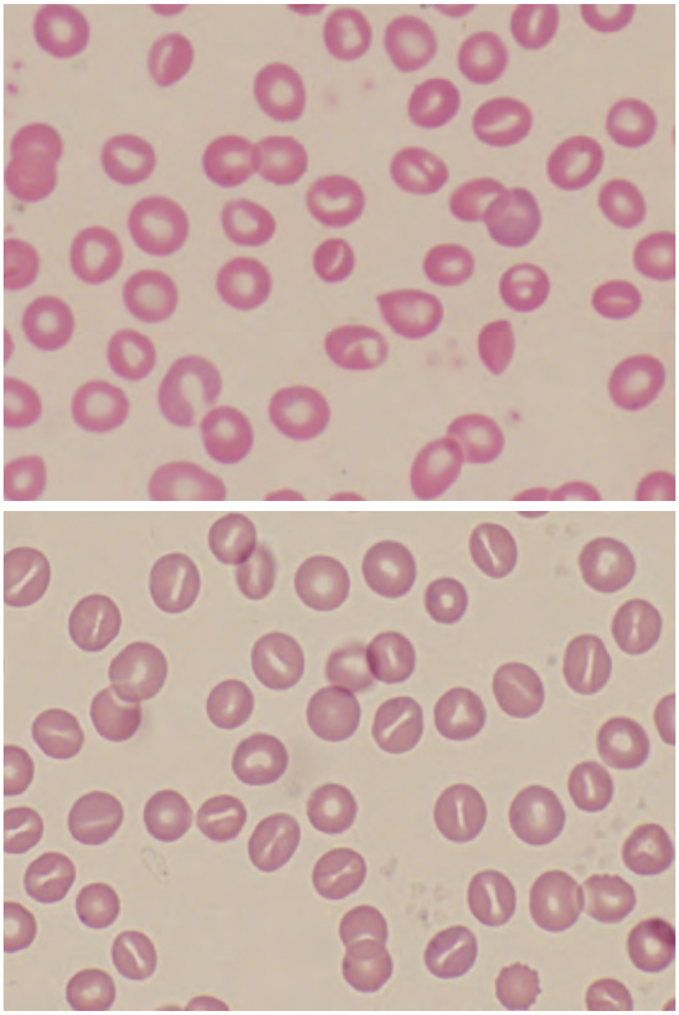

Figure 46.9 PERIPHERAL BLOOD SMEARS FROM PATIENTS WITH HEREDITARY XEROCYTOSIS (DESICCYTOSIS) AND STOMATOCYTOSIS (HYDROCYTOSIS). *(Top)* A Wright-stained peripheral blood smear from a patient with hereditary xerocytosis caused by a PIEZO1 mutation showing rare stomatocytes, occasional dessicytes—dense, abnormal erythrocyte forms where hemoglobin appears puddled at the periphery, and rare target cells. *(Bottom)* A Wright-stained peripheral blood smear from a patient with hereditary hydrocytosis is shown. Numerous stomatocytes, erythrocytes with a central mouth-like "stoma" are seen.

In some patients with hereditary hydrocytosis, missense mutations in RhAG, I61R, or F65S, have been found. In oocytes, these mutations induce a monovalent cation leak, possibly opening the pore of an ammonium transporter. Additional studies suggest that the F65S mutation exhibits a gain-of-function phenotype with increased cation conductance/permeability.

Splenectomy can improve, but not fully correct, the hemolysis. In some patients, splenectomy can be deleterious or even contraindicated (see later), perhaps because of altered endothelial cell adherence and membrane phospholipid asymmetry.

Hereditary Xerocytosis and the Intermediate Syndromes

Hereditary xerocytosis or desiccytosis describes an autosomal dominant hemolytic anemia characterized by RBC dehydration and decreased osmotic fragility. Affected individuals have characteristically moderate to severe hemolysis with an increased MCHC, reflecting cellular dehydration. Hydrops fetalis with fetal anemia or fetal ascites or the presence of pseudohyperkalemia have been reported in a number of xerocytosis kindred. Frequently, the MCV is mildly increased. In Coulter-type electronic counters, the conversion of pulse height (from the resistance of a cell passing through an electric field) to a cellular volume is dependent on cell shape. Xerocytes do not deform to the same degree as normal cells, causing the MCV to be approximately 10% too high. The peripheral blood film (see Fig. 46.9) does not always reveal stomatocytes (which are more prominent on wet films), but frequently, target cells, dessicytosis (dessicate), and spiculated cells are seen. In some of the cells, hemoglobin is concentrated ("puddled") in discrete areas on the cell periphery.

The mechanism of cellular dehydration is unclear and complex, involving a net potassium loss from the cells that is not accompanied by a proportional gain of sodium. Consequently, the net intracellular cation content and cell water are decreased. In some reports, a decrease in RBC 2,3-DPG has also been noted.

Most HX patients have heterozygous missense mutations in PIEZO1. In vitro studies of HX-associated PIEZO1 mutations demonstrate a gain-of-function phenotype, with many mutants demonstrating delayed channel inactivation, indicating increased cation permeability may lead to dehydration of HX erythrocytes. Piezo proteins are putative ion channels mediating mechanosensory transduction in mammalian cells. Animal models suggest mechanically activated Piezo1 plays a critical role in erythrocyte volume homeostasis. In a small subset of HX patients, defects of the Gardos channel encoded by the *KCNN4* gene have been described. Not surprisingly, when PIEZO1 mutations are co-inherited with other inherited anemias manifesting erythrocyte dehydration, such as sickle cell disease, marked erythrocyte dehydration worsens clinical severity.

Some of the reported cases of hereditary stomatocytosis share features of both hereditary stomatocytosis and xerocytosis categorized as "intermediate" syndromes. These patients characteristically have both stomatocytes and some target cells on the peripheral blood smear. Osmotic fragility is either normal or slightly increased. Sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the RBC volume are either normal or slightly reduced. These cells were reported to have subnormal glutathione content. In some patients, RBCs undergo in vitro hemolysis at 5°C, hence the designation *cryohydrocytosis*. A similar susceptibility to cold-induced cation permeability in which potassium and water loss predominates and xerocytes instead of hydrocytes are present has also been described.

A study of stomatocytosis, spherocytosis, and spherostomatocytosis patients whose erythrocytes demonstrated significant cation leaks at 0°C and in some cases band 3-deficient membranes revealed a series of missense mutations located in an intramembrane domain of band 3. In vitro studies suggest that these mutations convert band 3 from an anion exchanger to a nonselective cation leak channel.

Several investigators have also reported a dominantly inherited hemolytic anemia with stomatocytosis, occasional target cells, spherocytes, and a decreased osmotic fragility in which the main RBC membrane abnormality involved a nearly 50% increase in phosphatidylcholine and a corresponding decrease in phosphatidylethanolamine. Because abnormalities in membrane phospholipid composition have not been systematically investigated, it is uncertain whether the disorder represents a distinct disease entity.

The results of splenectomy in this group of disorders are variable. In some patients, the hemolytic anemia is improved, although often not fully corrected, by splenectomy, whereas in others, the severity of the hemolysis is unchanged. Splenectomy should be carefully considered in patients with hereditary stomatocytosis. Several patients with stomatocytosis (both hydrocytosis and xerocytosis) have developed hypercoagulability after splenectomy, leading to catastrophic thrombotic episodes or chronic pulmonary hypertension. Fortunately, the majority of persons with hereditary stomatocytosis are able to maintain an adequate hemoglobin level so that splenectomy is not required.

Rh Deficiency Syndrome

Rh deficiency syndrome designates rare individuals who have either absent (Rh_{null}) or markedly reduced (Rh_{mod}) Rh antigen expression, mild to moderate hemolytic anemia associated with the presence of stomatocytes, and occasional spherocytes on the peripheral blood film. Hemolytic anemia is improved by splenectomy.

The Rh antigens are present in ~20,000 to 30,000 copies per cell and reside on minor transmembrane proteins with an electrophoretic mobility of 28 to 33 kDa on SDS-PAGE. The Rh gene locus encodes two closely linked genes, one encoding the D polypeptide and the other encoding the CcEe proteins, and the antigenic expression of which is a consequence of alternate splicing of their pre-mRNA.

Rh proteins are part of a multiprotein complex that includes two Rh proteins and two Rh-associated glycoproteins (RhAG). Other proteins that associate with this complex include CD47, LW, glycophorin B, and protein 4.2. The Rh-RhAG complex interacts with ankyrin to link the membrane skeleton to the lipid bilayer. The Rh proteins share sequence homology to the Mep/Amt family of ammonium transporters in lower organisms and may participate in ammonium transport.

Rh_{null} erythrocytes have no Rh antigen and have reduced or absent LW, Fy5, Ss, U, and Duclos antigens. Rh, RhAG, LW, glycophorin B, CD47, and protein 4.2 are also reduced or absent. Rh_{null} erythrocytes have increased osmotic fragility, reflecting a marked reduction in membrane surface area. These cells are also dehydrated, as indicated by decreased cell cation and water content and increased cell density. The potassium transport and the Na^+/K^+ pump activity are increased, possibly because of reticulocytosis. Phospholipid asymmetry is also altered.

Although the clinical syndromes are the same, the genetic basis of the Rh deficiency syndrome is heterogeneous, and at least two groups have been defined. The amorph type is caused by defects involving the RH30 locus encoding the RhD and RhE polypeptides. The regulatory type of Rh_{null} and Rh_{mod} phenotypes results from suppressor or modifier mutations at the RH50 locus. When one chain of the Rh-RhAG complex is absent, the complex either is not transported to or is assembled at the membrane.

Familial Deficiency of High-Density Lipoproteins

Familial deficiency or absence of high-density lipoproteins (Tangier disease) because of mutations in ABCA1, a protein involved in cellular export of cholesterol, leads to accumulation of cholesterol esters in many tissues. Clinical manifestations include large orange tonsils, hepatosplenomegaly, lymphadenopathy, cloudy corneas, and peripheral neuropathy. Reported hematologic manifestations include a moderately severe hemolytic anemia with stomatocytosis and thrombocytopenia. Erythrocyte membrane lipid analyses reveal a low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in phosphatidylcholine at the expense of sphingomyelin.

Sitosterolemia

Sitosterolemia or phytosterolemia is a recessive disorder associated with elevated plasma levels of plant sterols. Affected patients exhibit xanthomatosis and early-onset premature cardiovascular disease. Reported hematologic manifestations include hemolytic anemia with stomatocytosis and macrothrombocytopenia. Mutations in the transporters ABCG5 or ABCG8 lead to gastrointestinal hyperabsorption and decreased biliary elimination of plant sterols as well as altered cholesterol metabolism. Plant sterols are not synthesized endogenously in humans but are passively absorbed in the intestine. ABCG5 and ABCG8 actively pump plant sterols out of the intestinal cells back into the intestine and out of liver cells into bile ducts. It has been hypothesized that the stomatocytic phenotype is caused by the intercalation of plant sterols into the inner leaflet of the lipid bilayer.

Acquired Stomatocytosis

Stomatocytes have been noted in diverse acquired conditions, including neoplasms, cardiovascular and hepatobiliary disease, alcoholism, and therapy with drugs, some of which are known to be stomatocytogenic in vitro. In some of these conditions, the percentage of stomatocytes on the peripheral blood smear can approach 100%. However, the clinical significance of this observation is unclear because stomatocytes are absent in most patients with the conditions listed. Furthermore, some stomatocytes can be found in normal individuals (3% to 5%). The most consistent association is that of stomatocytosis and heavy alcohol consumption.

RED CELL MEMBRANE VARIANTS AND INFECTIOUS DISEASE

Viral, bacterial, and parasitic infections can all cause anemia. Multiple mechanisms leading to hemolysis have been described. As mentioned earlier in this chapter, parvovirus B19 selectively infects erythroblasts through interaction with globoside, which encodes the P blood group antigen and temporarily shuts down erythropoiesis. Although this infection is tolerated well by healthy patients, it can lead to severe, at times life-threatening, aplastic crises in patients with anemias because of premature erythrocyte destruction. As one might predict, parvovirus cannot invade erythroblasts of the rare P-negative individuals.

Most infections cause hemolytic anemias triggered by several distinct, and at times overlapping, mechanisms. *Plasmodium, Babesia*, and *Bartonella* species directly attack the membrane and lyse the red cells. Some bacteria, such as *Clostridium perfringens*, elaborate hemolytic toxins or phospholipases that damage the membrane. Other infectious agents trigger the occasional production of autoantibodies against red cell membrane components, which in turn leads to autoimmune hemolytic anemia. Finally, many sepsis syndromes are associated with anemia because of disseminated intravascular coagulation.

Malaria and the Erythrocyte Membrane

The red cell membrane defects described earlier in this chapter cause mild to severe hemolytic anemias. At the same time, many red cell membrane alterations have developed as a defense against microorganisms and parasites invading and lysing red cells. This is especially true for malarial parasites. Although four different species of the malaria parasite *Plasmodium*, including *P. falciparum, Plasmodium ovale, Plasmodium vivax*, and *Plasmodium malariae*, infect humans, almost all of the 1.5 to 2 million annual deaths caused by malaria are attributable to *P. falciparum*.

Because malaria coexisted with humans over the course of human evolution, it comes as no surprise that multiple erythroid genotypes were selected that confer some level of resistance to infection or mitigate disease severity. The ensuing heritable phenotypes include, among others, resistance to red cell adhesion and/or invasion, slower intraerythrocytic growth, decreased or increased adhesion of infected red cells to vascular endothelium, and increased phagocytosis of parasitized red cells.

Malaria and other infections causing hemolytic anemias are described in more detail in Chapter 158, which also discusses hemoglobinopathies and red cell enzyme variants that reduce invasion and/or retard parasite growth. Consequently, we focus here on the heritable erythrocyte membrane alterations that developed as a defense against malaria.

Erythrocyte Preference

Two parasites, *P. vivax* and *P. ovale*, selectively infect reticulocytes, whereas *P. malariae* infects older erythrocytes. In contrast, *P. falciparum* infects red cells of all ages. This fact and the tendency of *P. falciparum*-infected erythrocytes to sequester in circulation explain the markedly higher severity of *P. falciparum* malaria.

Attachment and Invasion

Duffy Antigen

The *P. vivax* merozoite is completely dependent on attachment to the Duffy blood group antigen (also known as the *Duffy antigen receptor for chemokines [DARC]*) for erythrocyte invasion, and consequently, it cannot invade Duffy-negative RBCs. It has been hypothesized that this is why the Duffy-negative phenotype is common in large areas of Africa. The Duffy-negative phenotype is caused by mutation in a *GATA1* motif in the Duffy antigen gene promoter, preventing its expression in erythroid cells, leaving its expression in other tissues intact. Elucidation of this mutation explained a longstanding conundrum of transfusion medicine: why individuals with the Duffy-negative phenotype never develop antibodies against the Duffy antigen.

Glycophorins

All major erythrocyte glycophorins, A, B, and C/D, are involved in the attachment of *P. falciparum* to the RBC membrane. Consequently, invasion of *P. falciparum* into red cells from patients lacking glycophorin A (En[a−]), glycophorin B (S-s-U−), or glycophorins C and D (Gerbich negative, Ge−) is diminished. As noted earlier, the Gerbich-negative phenotype is associated with mild, asymptomatic ovalocytosis.

Protein 4.1R and Spectrin

Deficiency of protein 4.1R or self-association defects of spectrin are associated with elliptocytosis of varying severity. Both phenotypes appear to reduce the burden of RBC invasion.

Band 3 and Southeast Asian Ovalocytosis

Conflicting explanations of the basis of the protective phenotype of SAO (described earlier) from malaria have been described. Initial reports suggested that SAO erythrocytes were resistant to malarial invasion. These results were repeatedly questioned until recent studies demonstrated SAO cells to be resistant to invasion by the more virulent *P. falciparum* strains. This may explain the apparent contradiction with the reports of comparable parasitemias in SAO carriers and patients with a normal red cell phenotype from Papua New Guinea.

The protection from cerebral malaria afforded by SAO erythrocytes is likely because of the reduced cytoadherence of SAO red cells to the cerebral vasculature. Under conditions of flow, *P. falciparum*-infected ovalocytes adhere more strongly than normal infected red cells to the endothelial receptor CD36. Because this receptor is not expressed in the brain, this raises a possibility that ovalocytosis protects from cerebral malaria by diminishing the number of parasitized red cells available for adhesion to the cerebral vasculature via alternative receptors. Moreover, ovalocytes appeared resistant to invasion by parasite strains that tend to bind to intracellular adhesion molecule I (ICAM1), the likely receptor for cytoadherence in the brain, but the exact mechanism is not yet known.

Knops Blood Group System

Severe malaria, particularly cerebral malaria, has been associated with the formation of rosettes, clumps of cells formed by the adhesion of malaria-infected erythrocytes to complement receptor 1 (CR1) on uninfected erythrocytes. Identification of the Knops blood group antigens on CR1, followed by observations that frequencies of various Knops antigens varied significantly in Whites and individuals of African ancestry, led to the hypothesis that some Knops group antigens might be protective from rosetting and severe malaria. Case-control studies with genotyping and/or flow cytometry have yielded conflicting results, but several have linked low-expression CR1 alleles with malaria resistance. Further studies have shown that the expression of CR1 and other complement proteins increases with age. Together these data suggest that genetic and age-related differences in complement protein expression contribute to the variability observed in individuals with severe malaria.

Although these erythrocyte membrane polymorphisms offer fascinating insight into natural defenses against one of the most serious diseases affecting humans, the mechanism of resistance to malaria has not been fully elucidated for any of them. Malaria has clearly had a profound impact on the genetic makeup of populations living in endemic areas and provided us with multiple clues about the host-parasite relationship. Better understanding of these natural defenses might eventually be converted into effective therapeutic interventions.

CHAPTER 47

AUTOIMMUNE HEMOLYTIC ANEMIA

Marc Michel and Ulrich Jäger

Autoimmune hemolytic anemia (AIHA) is a rare autoimmune disease caused by autoimmune-mediated destruction of red blood cells (RBCs) by autoantibodies with various properties and target specificities. Exact laboratory diagnosis may sometimes be difficult; therefore, experienced diagnostic reference centers play an important role. The disease can be primary (idiopathic) or caused by an underlying condition (secondary), including systemic autoimmune diseases, infections, primary immunodeficiencies, drugs, or neoplasms (mostly lymphomas). The clinical course of the disease as well as treatment decisions are influenced by the type of antibody involved. Currently, treatments for AIHA are still mainly based on experience and opinion as opposed to robust evidence and there is still no therapy licensed for AIHA. Several guidelines have been proposed. Recommendations for diagnosis and treatment by an international group of experts were recently published. Management of the disease still requires general hematologic skills as well as knowledge of diagnostic criteria and treatment options. In the last years, new promising treatment approaches have been developed.

HISTORY

The history of diagnostic and therapeutic progress in AIHA has been described by Dacie,[1] one of the great pioneers in this field. Milestones were the discovery of the first RBC autoantibody (Donath–Landsteiner [DL] antibody) in 1904, the introduction of the Coombs test in 1945, the establishment of splenectomy as an effective treatment of AIHA in the 1950s, and the finding that rituximab was an effective treatment in the past decade. The diagnosis and treatment of patients with AIHA were reviewed by several authors.[2–8]

EPIDEMIOLOGY

Based on the characteristics and thermal amplitude of autoantibodies, AIHAs are usually classified as either warm (wAIHA) or cold (cAIHA). A low proportion of patients achieve spontaneous or treatment-induced, long-term remissions; overall mortality is relatively low[9–11] and the prevalence of AIHA has been estimated as 17 in 100,000 in Denmark.[12] The incidence of AIHA in children and teenagers is 0.2 to 1.0 per million per year.[9] There is some evidence of a genetic predisposition and/or familial clustering of AIHA/Evans syndrome in children, but no clear genetic background has been identified for the majority of patients.[13]

Primary AIHA and Evans syndrome are slightly more prevalent in adult females and in children.[10,14] In secondary AIHA, the female-to-male ratio is very high in systemic lupus erythematosus (SLE), but close to 1 in chronic lymphocytic leukemia (CLL)-associated AIHA. The incidence of chronic cold agglutinin disease (CAD) is estimated to be approximately 1 to 2 per million per year with a female prevalence.[15] Geographical differences have been suggested with a higher incidence of CAD in Northern climates, potentially explained by a higher number of symptomatic patients in these areas.

PATHOBIOLOGY

Hemolysis is initiated when an autoantibody binds to the one or several RBC membrane antigens and promotes antibody-dependent, cell-mediated cytotoxicity, and/or recruits and activates complement. Destruction of the RBC can occur directly in the circulation (intravascular hemolysis) and/or by removal of the cell by macrophages in the spleen, liver, or both (extravascular hemolysis) (Fig. 47.1). Several immunoglobulin (Ig) subclasses can fix complement and activate the classical complement (Ct) pathway: IgG3 activates Ct more efficiently than does IgG1, whereas IgM, which is a potent Ct activator, is usually eluted ex vivo and therefore not found on RBC membrane by the direct antiglobulin test (DAT). Macrophages recognize opsonized erythrocytes via receptors specific for the Fc fragment of IgG, namely Fcγ receptors (FcγRs) and for C3d. RBCs coated with IgG or complement alone are destroyed in the spleen and liver, IgG-coated cells in the spleen, and IgM-coated cells in the liver.[16,17] This has major implications for treatment, particularly for the effect of steroids and splenectomy.

Warm Antibody Hemolytic Anemia

wAIHAs represent 60% to 80% of all AIHAs. The RBC antibodies in wAIHAs are mostly polyclonal IgG1 or IgG3, which are able to activate the complement system (Table 47.1). The DAT in wAIHAs is positive either with IgG (37%) or IgG + C3d (43%). Rarely, the DAT is only positive with C3d (when the amount of IgG on the RBCs is very small or in case of “warm,” IgM autoantibody). Patients with IgG antibodies may have also IgA antibodies, but IgA antibodies without IgG antibodies are a very rare cause of wAIHAs. wAIHAs are often directed against Rh antigens, but also against other RBC’s membrane antigens (non-Rh–related autoantibodies) such as band 3 protein or glycophorin A. The antibodies fix complement and bind tightly to the RBCs at 37°C. Therefore, only a small amount of antibody is detectable in the serum. The antibody-coated RBCs are removed from the circulation by splenic (to a lesser degree also by hepatic) macrophages via FcγRIII receptors. IgG_3 and IgG_1 have the highest affinity for the Fc receptors of macrophages. Erythrocytes that are only partially phagocytosed by macrophages become spherocytes, which are removed in the splenic cords because of their rigid structure and can be easily detected on peripheral blood smear. Destruction of RBCs may also be caused by other mechanisms such as antibody-dependent cellular cytotoxicity as well as complement-dependent cytotoxicity when complement activation is involved.[18]

IgM wAIHAs are a very rare cause of AIHA. This type of AIHA can be suspected if RBC autoagglutination occurs at room temperature. The DAT result is positive with C3d alone (65%) or with IgG (24%), there are no detectable cold agglutinins (CA) in the serum. Using sensitive methods, IgM on the RBCs can be detected in 71%.[19] Non-Hodgkin lymphoma (NHL) is the underlying disease in some of these cases. This AIHA is often life-threatening and refractory to steroids and splenectomy.

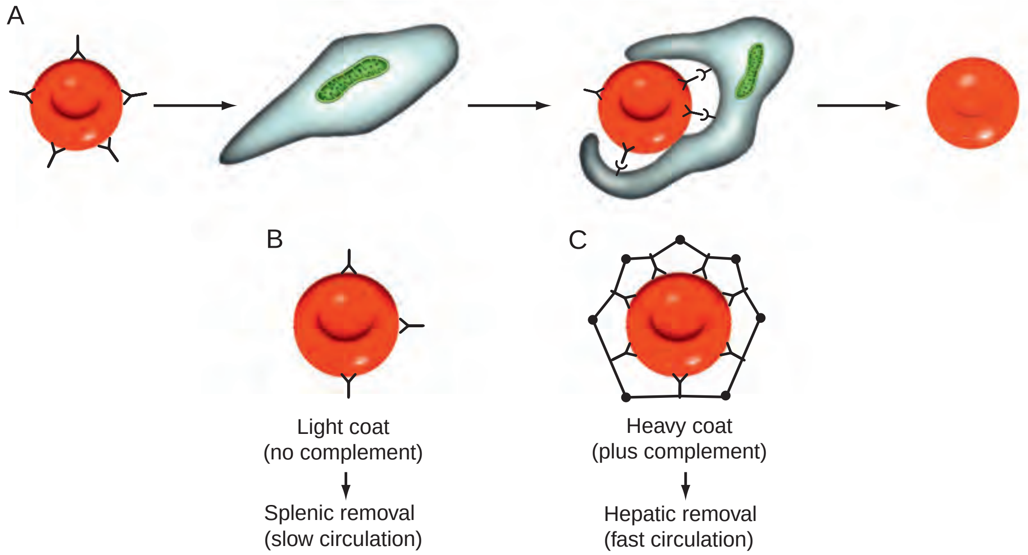

Figure 47.1 MECHANISM OF EXTRAVASCULAR HEMOLYSIS IN AUTOIMMUNE HEMOLYTIC ANEMIA. (A) Macrophage encounters an IgG-coated erythrocyte and binds to it via its Fc receptors. Thus entrapped, the red blood cell (RBC) loses bits of its membrane as a result of digestion by the macrophage's ectoenzymes. The discoid erythrocyte transforms into a sphere. (B) RBCs lightly coated with IgG (and therefore incapable of activating the complement cascade) are preferentially removed in the sluggish circulation of the spleen. (C) RBCs with a heavy coat of IgG; thus, C3b *(black circles)* can be removed both by the spleen and the liver. (*Courtesy Cunningham MJ, Silberstein LE. Autoimmune hemolytic anemia. In: Hoffman R, Benz EJ Jr., Shattil SJ, et al., eds. Hematology: Basic Principles and Practice. 4th ed. Philadelphia, PA: Elsevier; 2005.*)

TABLE 47.1 **Properties and Specificities of Red Blood Cell Autoantibodies**

	Immunoglobulin (Subclass)	Type of Antibody	Clonality	Specificity	Hemolysis	Predominant Site of Removal of Red Blood Cells
wAIHAs	$IgG_{(1–4)}$, IgA	Incomplete	Mostly polyclonal	Rh-antigens and non-Rh-antigens	Extravascular	Spleen (liver)
cAIHAs	IgM	Complete	Mostly clonal	Anti-i, -I^T, -I, -Pr	Intravascular	Liver
Donath–Landsteiner antibody	IgG	—	Polyclonal	P antigen	Intravascular	—

cAIHA, Cold autoimmune hemolytic anemia; *Ig,* immunoglobulin; *wAIHA,* warm autoimmune hemolytic anemia.

Cold Antibody Hemolytic Anemia

Cold antibodies in primary or secondary chronic forms of cAIHA (known as cold agglutinin disease or CAD) are usually monoclonal IgM. The IgM has two binding sites for C1q and fixes complement easily. The targets are polysaccharides (I, I^T, I, or Pr antigens). The "i" antigen is a nonbranched polysaccharide in the cord blood and the "I" antigen is a similar but a branched molecule expressed in the RBCs of adults. Cold antibodies, more commonly known as "CAs," bind to the RBCs at low temperatures and cause their lysis at temperatures above 22°C. The DAT is typically positive with C3d alone. When CAs are present at high titers, they may activate the complement system directly, produce a membrane attack complex, and produce intravascular hemolysis with hemoglobinuria. Usually complement-coated RBCs are sequestered by liver macrophages.

Some forms of transient cAIHA triggered by an infection may rarely occur, they can classically be associated with a *Mycoplasma pneumoniae* infection or yet with some viral infections (mostly EBV or CMV). The onset is usually abrupt and the degree of anemia may be severe with transfusion requirement, but the outcome is most often good within few weeks.

Lastly, paroxysmal cold hemoglobinuria (PCH) is a very rare form of AIHA caused by the DL antibody. This is a rare, usually polyclonal IgG cold antibody to P antigen (glycosphingolipid globoside), which binds to the RBCs at 4°C. The cells are lysed at higher temperatures. The DAT is positive with C3d, no CAs are present, and the diagnosis can only be ascertained by means of the DL test in a specialized lab. In this test, normal RBCs and patient and normal serum are incubated at 4°C. Agglutination occurs after warming to 37°C. The prominent clinical feature of PCH is a brisk, immediate but sometimes also delayed hemoglobinuria after cold exposure even in patients with low antibody titers. In the past, it has been associated with viral infections in children and secondary or tertiary syphilis in adults. Now, two types can be distinguished clinically[20]: (1) an acute, severe form (often associated with hemoglobinuria) but self-limiting AIHA after (respiratory) infections in children, and (2) a rare, chronic AIHA in nonsyphilitic persons with various underlying conditions, including NHL. Patients with chronic PCH respond poorly to steroids and splenectomy.

Mixed Warm and Cold Autoimmune Hemolytic Anemia

A small number of patients have an AIHA mixed with a positive DAT for both IgG and C3d, indicating coexistence of warm IgG autoantibodies and high-titer CAs (titer >1/64).[21] Mixed AIHAs have a severe course of disease and lower median hemoglobin (Hb) values (5.8 g/dL) that frequently require multiple therapy.[10]

Atypical Autoimmune Hemolytic Anemia

The term characterizes DAT-negative, IgA-driven, or warm-IgM forms. They represent a diagnostic challenge, resulting in delayed treatment.[22,23]

ETIOLOGY AND PATHOPHYSIOLOGY

Our knowledge about the etiology of AIHA is still limited. Factors that may play a role are antigen mimicry; immune deficiency; and, to a lesser extent, probably genetic factors. AIHA, similar to other autoimmune diseases, is a consequence of the loss of immunologic (self-) tolerance against antigens expressed on the erythrocyte surface. Production of RBC antibodies is a result of the interaction of T and B cells, as well as regulatory factors (e.g., T-regulatory cells, cytokines[24]). Disturbances of the Th1/2 T-cell subset balance with IL-10/IL-12 imbalance toward Th2 cells as well as the occurrence of clonal regulatory T cells specific for a RBC autoantigen have been described.[25–27] Moreover, BAFF-dependent B-cell and plasma-cell activation plays a role with the possible emergence of long-lived autoreactive plasma cells.[28]

This may be linked to the fact that AIHA does not only occur in immunocompetent individuals but frequently occurs in patients with acquired B or T-cell defects such as CLL, common variable immunodeficiency (CVID), HIV infection, or immunosuppressive therapy, particularly after stem-cell or solid-organ transplantation. Polymorphisms or altered expression of negative regulators of T-cell responses such as cytotoxic T lymphocyte antigen 4 (CTLA4) or interleukin-10 may also play a role. Mouse models (New Zealand black mice) have revealed an association of genetic loci with antierythrocyte antibody production or cold agglutinin escape tolerance after *Mycoplasma* infection.

Various target antigens have been described, with Rhesus polypeptides, glycophorin A, and erythrocyte band 3 being the most prominent in wAIHA. Cold reactive antibodies frequently target the I or i blood group-specific antigens. Events linked to the development of secondary AIHA by induction of cross-tolerance (molecular mimicry) are infections (*M. pneumoniae* [I antigen target], parvovirus B19, herpes viruses), neoplastic diseases (paraneoplasia), and drugs by various mechanisms. Important differences exist in the pathogenesis of wAIHA and cAIHA. The pathogenesis of primary wAIHA is largely unknown. Secondary wAIHA is a complication of several congenital or acquired immune deficiencies. Both moderate (e.g., in CLL) and severe (HIV, post-transplant, congenital severe T-cell deficiencies) T-cell and humoral immune deficiency predispose to wAIHA, but no correlation has been established between the type and severity of immune deficiency and the risk of AIHA. One poorly understood phenomenon is the lack of a clear relationship between the presence of RBC antibodies and anemia. In many instances, no anemia is present despite a strongly positive DAT or high titers of cAIHAs. There is also only a poor correlation between antibody titers and severity of anemia. Another unexplained finding in secondary AIHA is the occurrence of both wAIHAs and cAIHAs in the same condition, for example, in lymphomas or infections.

Antibodies in primary AIHA are frequently polyreactive and polyclonal (no clonal B cells detected by polymerase chain reaction [PCR]). Antibodies in CAD are mostly produced by PCR-detectable, oligoclonal, or monoclonal B-cell populations. The nature of these antibodies has been extensively studied in CAD. However, in only a few cases has it been established that the RBC antibody is clonal. In most reports, clonality of RBC antibodies was assumed if the patient had a paraproteinemia.

B-cell neoplasms, expressing IgMκ antibodies, directed against RBC antigens have few somatic mutations, which seem to be fairly restricted to certain Igheavy and light-chain families (VH4–34, VκIV).[29] Moreover, a VH4–34 CLL confounding subclone was shown to arise from a pre-existing CAD-producing, B-cell population. The restricted clonality of CAD-producing B cells is further corroborated by the detection of clonal Ig rearrangements and recurrent chromosomal aberrations (trisomy 3).[30,31] CLL cells may also drive AIHA by presenting the autoantigen (e.g., erythrocyte protein band 3) to T cells.

SYMPTOMS, CLINICAL FINDINGS, AND RISKS

The symptoms of AIHA depend on the type of antibody, the mode of onset, and the severity of anemia. In patients with wAIHA, the onset is mostly gradual or subacute and the symptoms (i.e., tiredness, reduction of physical activity, jaundice, and shortness of breath in elderly patients) are attributable only to anemia. However, patients with postinfectious, drug-induced AIHA or patients with DL or Pr antibodies often present with acute severe symptoms such as malaise, fever, jaundice, abdominal pain, shortness of breath, and hemoglobinuria. The course in such patients may be fulminant and even fatal. Patients with chronic cAIHA (CAD) often have a rather indolent course. Symptoms suggestive of cAIHA are cold sensitivity, cold-dependent acrocyanosis, acral numbness, and rarely livedo reticularis. Anemia worsens after cold exposure or after conditions associated with an acute phase reaction such as infections.

During clinical examination, a subicterus may be seen. Lymphadenopathy, important splenomegaly, or any organomegaly is rare in patients with primary AIHA. Its presence suggests secondary AIHA.

Patients with wAIHA are at an increased risk of venous thromboembolism, sometimes associated with a lupus anticoagulant (LA).[10,32] Older patients with AIHA are at an increased risk of cardiovascular complications, which may also be partly caused by the treatment.

LABORATORY DIAGNOSIS OF AUTOIMMUNE HEMOLYTIC ANEMIA

AIHA is essentially a laboratory diagnosis. The diagnostic pathway of AIHA should proceed in a stepwise fashion answering the following questions.

FOUR IMPORTANT QUESTIONS FOR THE DIAGNOSIS AND MANAGEMENT OF AUTOIMMUNE HEMOLYTIC ANEMIA

It is of utmost importance to differentiate between various types of autoimmune hemolytic anemia (AIHA). A step-wise approach helps in making the right decisions:

Question 1:

Hemolytic anemia? The basic features of hemolytic anemia are low haptoglobin levels, elevated indirect bilirubin, and elevated lactate dehydrogenase. Reticulocytosis is a common feature (≈80% of the cases) of AIHA reflecting the increase of erythropoiesis in response to accelerated destruction of red blood cells (RBCs).

Question 2:

Autoimmune hemolytic anemia? A direct antiglobulin test (DAT) is initially performed with a polyspecific antibody to detect IgG or complement C3d bound to RBCs. If the DAT result is positive, the diagnosis of AIHA is established in the absence of any other cause of hemolysis and/or any recent transfusion. In parallel, the peripheral blood smear is very helpful because it may show the presence of spherocytes (wAIHA) or agglutinates (cAIHA) and show the absence of schizocytes.

Question 3:

Warm or cold autoimmune hemolytic anemia? The DAT is further elaborated with monospecific antibodies to IgG and complement (C3d). If the DAT result is positive with IgG alone or with IgG + C3d, the AIHA is most probably caused by a warm antibody (wAIHA). If the DAT is positive with C3d only, the AIHA is most probably caused by a cold antibody (cAIHA).

Question 4:

Primary or secondary AIHA? More than half of wAIHAs are secondary to underlying diseases. Secondary AIHA should be suspected in patients with additional findings or who are refractory to initial steroid treatment. In this case, the underlying disease has to be diagnosed (e.g., by serologic tests, computed tomography (CT) scan, or bone marrow biopsy).

Diagnostic Steps

The first step is to establish the diagnosis of hemolytic anemia (see box on Four Important Questions for the Diagnosis and Management of Autoimmune Hemolytic Anemia). This diagnosis is established by the presence of the following pentad of findings: normocytic or macrocytic anemia (male Hb <13.0 to 14.0 g/dL; female <12.0 g/dL), reticulocytosis (corrected reticulocyte count >2% or absolute reticulocyte count >100,000/μL to 120,000/μL), low haptoglobin, elevated lactate dehydrogenase (LDH), and elevated unconjugated (indirect) bilirubin. Haptoglobin is an α2-globulin that binds Hb. This Hb–haptoglobin complex is degraded in the liver. Hemopexin is another plasma protein with a very high binding affinity to Hb. It scavenges heme released from RBCs and protects the organisms from the adverse effects of circulating Hb. The determination of hemopexin is not essential for the diagnosis of AIHA. Indirect bilirubin is usually not more than 5 mg/dL except in associated liver disease (Epstein-Barr [EBV]-associated AIHA). Additional findings are increased urobilinogen in the urine and spherocytes in the blood smear (Fig. 47.2). Leukoerythroblastosis occurs only in peracute AIHA, but microangiopathic hemolytic anemia should always be suspected in such cases. Bone marrow examination is usually not necessary except in patients in whom secondary AIHA, in particular lymphoma, is suspected. RBC survival is shortened, but its measurement with radioisotopes has no diagnostic value, not even for the prediction of the efficacy of splenectomy.

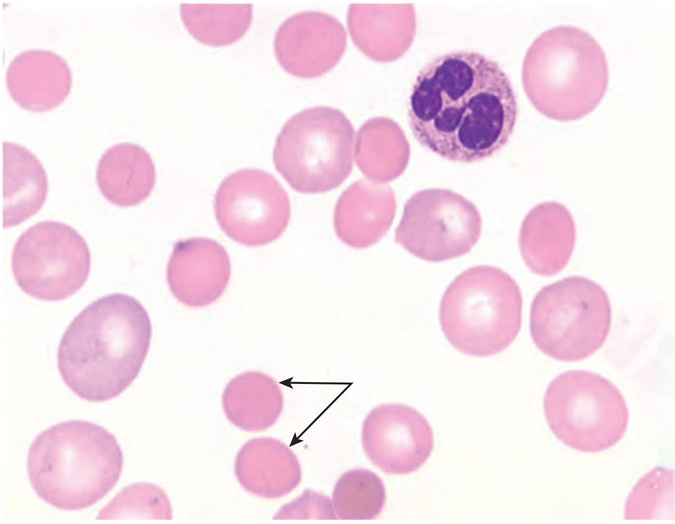

Figure 47.2 BLOOD SMEAR SHOWING NUMEROUS SPHEROCYTES *(ARROWS)*.

Step 1: Hemolytic anemia?

Among methodologic diagnostic problems, reticulocyte counting is the biggest because in many laboratories low-precision microscopic counts are still performed. Automatic-flow cytometric methods are more precise, reliable, and convenient. With flow cytometry, the number of highly fluorescent reticulocytes can also be measured. Falsely very high mean corpuscular volume (MCV) and mean corpuscular Hb concentration occur in some cases of cAIHA because RBC counts are falsely low because of agglutination of RBC at room temperature (Fig. 47.3). If a cAIHA is suspected, blood samples should be sent as quickly as possible to the laboratory in warmed containers.

All of the findings of the pentad are not always present. Reticulocytosis is often (in ≈20%) not present at the onset of AIHA. This is mostly because of a delayed initial bone marrow response of erythropoiesis. After 1 week, most of these patients have reticulocytosis. In other patients (particularly in secondary cases), absence of reticulocytosis may be attributable to impairment of erythropoiesis caused by bone marrow infiltration, vitamin B_9 or B_{12} deficiency or blunted erythropoiesis caused by an acute-phase reaction. If the reticulocyte count is very low, pure RBC aplasia (PRCA), either immune mediated or induced by a parvovirus (or HHV6) infection, should be suspected. Haptoglobin may be falsely normal or even slightly increased, particularly in patients with malignant or immune diseases, because haptoglobin is an acute-phase protein. Haptoglobin may be falsely low in patients with a haplotype H_0H_0 and in patients with severe liver disease. Both increased bilirubin and elevated LDH have a limited specificity for AIHA.

Step 2: Autoimmune Hemolytic Anemia?

The next step is to find out whether the hemolytic anemia is an AIHA. This is best done by the DAT (Fig. 47.4). In this test, washed RBCs of the patient (obtained from an ethylenediaminetetraacetic acid [EDTA] blood sample) are incubated in a tube with a

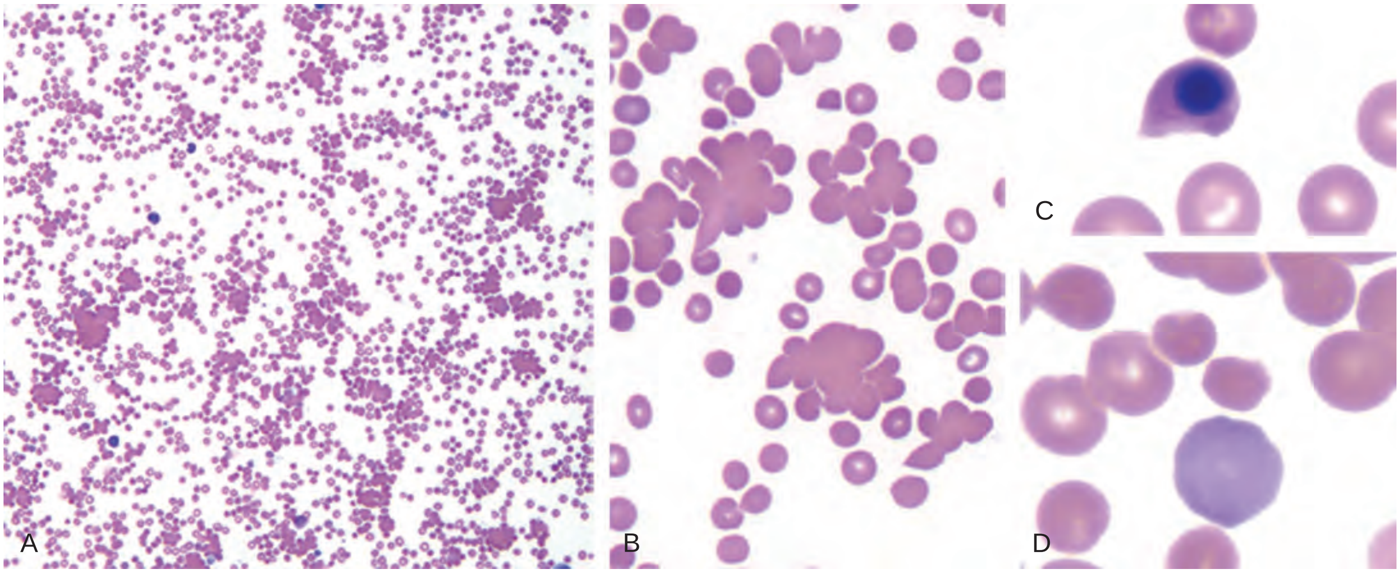

Figure 47.3 PERIPHERAL SMEAR IN COLD AGGLUTININ DISEASE. Low-power scan shows uneven distribution of red blood cells (RBCs) (A), which at slightly higher power (B) shows the RBCs to be clumped together or agglutinated. This must be distinguished from rouleaux formation. High-power scan shows nucleated RBCs (C), polychromatophilia, and microspherocytes (which are mostly seen in wAIHA) (D).

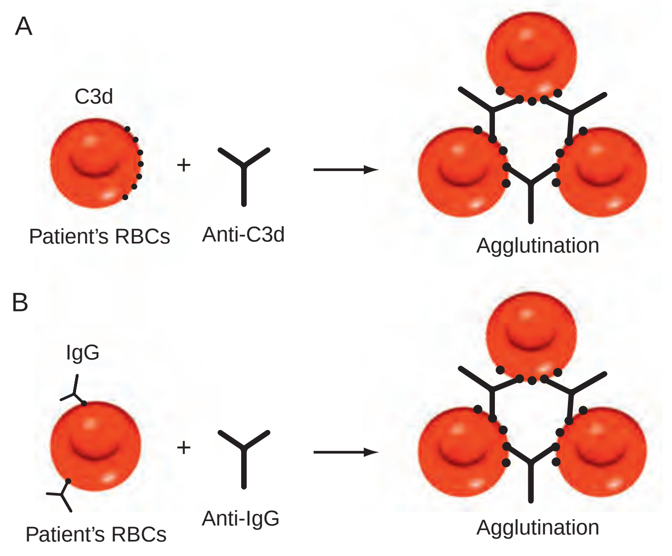

Figure 47.4 DIRECT ANTIGLOBULIN TEST FOR DETECTION OF (A) ERYTHROCYTE-BOUND C3d OR (B) IgG. Hemagglutination occurs when anti-C3d or anti-IgG can create a lattice structure by bridging sensitized RBCs. *IgG*, Immunoglobulin G; *RBC*, red blood cell. *(Courtesy Cunningham MJ, Silberstein LE. Autoimmune hemolytic anemia. In: Hoffman R, Benz EJ Jr, Shattil SJ, et al., eds. Hematology: Basic Principles and Practice. 4th ed. Philadelphia, PA: Elsevier; 2005.)*

polyspecific antibody to IgG and complement (C3d). If the RBCs agglutinate, the test result is positive. In many laboratories, the tube test has been replaced by the tube-gel test, which is easier to perform, more reliable, and probably more sensitive (Fig. 47.5). In the indirect antiglobulin test (IAT), patient plasma or serum is incubated with test RBCs and (after washing) RBC-bound IgG is detected with the DAT. IAT is usually not required for the diagnosis of AIHA except when a drug-dependent antibody is suspected. For the differentiation of drug-dependent antibodies and autoantibodies, an acid eluate of the patient's RBCs should be made and tested in the IAT. If the IAT result is positive, the patient has autoantibodies. The severity of AIHA does not correlate with the strength of the DAT, but rather with the Ig subclass of the antibody (IgG_1 or IgG_3). The result of the DAT is not a reliable marker of treatment success because patients with a complete hematologic remission may remain DAT positive, and DAT positivity or negativity has only limited value to predict the duration of hematologic remission.

Falsely Negative and Positive Direct Antiglobulin Test Results Without Hemolysis or Anemia

If the conventional DAT test result is negative, hemolytic anemia is defined as DAT-negative. This implies that positive DAT with anti-IgA has been excluded as well as other causes or hereditary of acquired hemolytic anemia—in particular hereditary spherocytosis and paroxysmal nocturnal hemoglobinuria. However, AIHA cannot be definitely excluded because about 5% (2% to 11%) of AIHA patients are DAT negative. If AIHA is suspected for clinical grounds despite a negative DAT result, more sensitive quantitative tests are required to determine the amount of IgG on the RBCs. The threshold of positivity of the conventional DAT is 100 to 200 IgG molecules per RBC, but in some AIHA patients the RBC IgG is less than this amount. In about one-third of DAT-negative cases, one of the more sensitive test results (e.g., immunoradiometric tests) will be positive. However, the relationship between the amount of RBC IgG and hemolysis is not clear cut, and there is no "hemolysis threshold."[33] The reasons for these discrepancies between the in vitro and in vivo activity of RBC antibodies are largely unknown. Differences in macrophage activity may be one possible explanation. A search for antibodies in the RBC eluate in which antibodies are more concentrated is also useful. IgA antibodies are rare and sometimes not included in the analysis. Finally, there is the possibility of low-affinity antibodies. Such antibodies are washed out when the washes are made with 37°C saline. A high rate of DAT-negative AIHA has been observed in AIHA induced by nucleoside analogues, but also in other secondary AIHA.

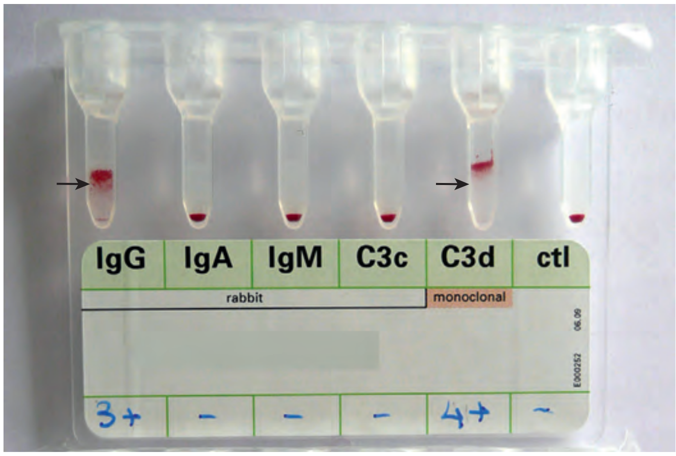

Figure 47.5 RESULT OF A DIRECT ANTIGLOBULIN TEST PERFOMED ON GEL COLUMNS, WITH A POSITIVE RESULT SHOWN WITH AN ANTI-IgG AND ANTI-C3d. *ctl*, Control; *IgA*, immunoglobulin A; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M.

The DAT result is positive in 1 in 10,000 to 3 in 10,000 normal persons and 10% of hospital patients without anemia or signs of hemolysis.[34]

Step 3: Warm or Cold Autoimmune Hemolytic Anemia?

In a further step, the DAT is carried out with monospecific antibodies to IgG and complement (C3d) to find out whether a warm or cold antibody is the cause of hemolysis. If the DAT result is positive with IgG alone or with IgG plus C3d, the AIHA is most probably a wAIHA. If the DAT result is positive with only C3d, the AIHA is most probably a cAIHA. The differentiation between wAIHAs and cAIHAs is extremely important for the choice of treatment.

Some special diagnostic problems exist when it comes to cAIHAs. If cAIHA is suspected, it must be taken care that the blood sent to the laboratory is kept at 37°C to get reliable results. Patients with only RBC C3d may (rarely) have wAIHAs when the amount of RBC IgG is very small. In patients with C3d positivity, the cold agglutinin titer should be determined. If it is equal or greater than 1:64 the diagnosis of a CAD is established. There is no consensual threshold titer that separates normal from abnormal. If the titer is less than 1:64, the thermal amplitude of the antibody must be determined. If the thermal amplitude is above 22°C, the diagnosis is CAD. Mixed type AIHA is rare. Frequently used criteria are a positive IgG DAT result and a positive eluate result plus a C3d-positive DAT result and the presence of CAs with a thermal amplitude of greater than 30°C or high titer Cas (>1:40). Many published cases of mixed-type antibodies do not fulfill these criteria.[35,36]

Step 4: Primary or Secondary Autoimmune Hemolytic Anemia?

In the last diagnostic step, it must be determined whether the AIHA is primary or a complication of an underlying disease (secondary). About half of cases of AIHA (or probably even more) are secondary. The main causes are systemic immune diseases and malignancies and mostly B-cell lymphomas. Other underlying conditions are infections, primary immunodeficiencies, drugs, transplantation, and congenital defects. The decision regarding which diagnostic procedures should be used for this purpose depends mainly on the type of AIHA (wAIHAs or cAIHAs) and should include history, physical examination, laboratory tests, and imaging procedures if indicated. In children and younger patients with wAIHA, evidence for an infection should be sought. A list of all recent medication should be made. A history of weight loss, fever, or poor general condition, and arthritis points to a malignancy or systemic immune disease as the underlying condition. Palpable lymphadenopathy and important splenomegaly do not belong to the usual clinical picture of primary wAIHA. In this case, lymphoma (particularly splenic marginal zone lymphoma [SMZL]) should be suspected. Laboratory tests should include acute-phase proteins, LDH, quantitative determination of Igs, antinuclear antibodies, and other tests guided by the clinical history. A bone marrow examination is not obligatory except when lymphoma is suspected. Abdominal ultrasonography or a CT scan is reasonable in all cases to look for a disproportionate splenomegaly, the remote (but important) possibility of an ovarian teratoma (in women), another solid tumor, lymphadenopathy, or solitary extranodal lymphomas. An activated partial thromboplastin time with a lupus-sensitive reagent may reveal an LA. Fluorescence-activated cell sorting or PCR for the detection of monotypic/monoclonal lymphocytes may be done, but the clinical usefulness of such tests to guide treatment decisions is uncertain.

In cAIHA, a history of a febrile illness should prompt a thoracic radiography, and if results are positive, a serologic test for mycoplasma pneumoniae is required. The quantitative determination of serum Igs and a search for a clonal Ig by immune fixation are important. If immune fixation findings are positive, a search for lymphoma is necessary, which may include bone marrow biopsy even when there is no lymphadenopathy. In addition to classical CAD, CAs occurring in association with other cancers, aggressive lymphomas, or infection should be termed *cold agglutinin syndrome*.[37]

Other tests, including blood glucose, Hba_{1c}, renal and hepatic function tests, HIV serology, hepatitis B antigen, and exclusion of latent tuberculosis are necessary to avoid complications of steroids (in wAIHAs) or rituximab (in cAIHAs and wAIHAs).

IMMUNOLOGIC PHENOMENA ASSOCIATED WITH AUTOIMMUNE HEMOLYTIC ANEMIA

Evans syndrome is the simultaneous or sequential combination of wAIHAs with autoimmune thrombocytopenia (ITP) ± autoimmune neutropenia, a typical but rare association. Platelet antibodies are usually directed against glycoprotein IIB/IIIA. Autoimmune neutropenia occurs in 25% of patients. There is no sex predilection; about half of the cases are secondary. Evans syndrome is relatively more common in patients with SLE, antiphospholipid antibodies (APAs), CVID, and autoimmune lymphoproliferative syndrome (ALPS).[38] A search for an ALPS is mandatory in younger patients with Evans syndrome. In roughly 50% of the cases, AIHA and ITP occur simultaneously; in the others disease starts with either ITP or AIHA. There may be an interval of several years between the onset of AIHA and ITP.[39]

wAIHA, cAIHA, or a positive DAT result without anemia may be associated with PRCA. PRCA may be either immune mediated such as in T-cell neoplasms (particularly T-cell large granulocytic leukemia or thymoma) or may be caused by an infection with parvovirus B19. Patients with parvovirus-associated AIHA often present with PRCA.

AIHA is definitely associated with APAs and LA. In one single-center, prospective study, LA was found in 30% predominantly idiopathic AIHA. AIHA (4%) and Evans syndrome (10%) are frequent in patients with APAs. It is well established that patients with AIHA have a significantly (2.8-fold to 3.8-fold) elevated risk of venous thromboembolism, especially during the active phases of the disease.[32] It is likely, but not proven, that patients with AIHA associated with LA are at a higher risk.

In lymphomas, some cases of AIHA are associated with C1-esterase inhibitor deficiency and mixed cryoglobulinemia.

Temporal Relationship of Secondary Autoimmune Hemolytic Anemia to the Underlying Condition

The temporal relationship of AIHA to an underlying condition is complex. AIHA antedates the diagnosis of malignancy in many cases—including NHL—sometimes for years. In population-based studies, clonal B cells have been detected in some patients with seemingly "idiopathic," AIHA. In most instances, AIHA occurs concurrently with the malignancy. In some other cases, AIHA occurred only at the recurrence and rarely in complete remission (CR) after successful treatment. In CLL, AIHA occurs preferentially in a late and active phase of the disease. The patients have poor prognostic factors and often have been treated with various agents.

In immune diseases, particularly SLE, AIHA is a complication of the early phase of the disease. Infection-related AIHA occurs shortly after the onset of symptoms, except in HIV infection in which AIHA is a complication in the late advanced stage of the disease.

In CIVD, AIHA or Evans syndrome preceded or revealed CVID in more than half of the cases.

Serologic Type of Autoimmune Hemolytic Anemia in Secondary Autoimmune Hemolytic Anemia

It is an interesting phenomenon that in underlying diseases associated with AIHA, all serologic types of AIHA may occur, but usually one serologic type (wAIHA, cAIHA, or DL antibody) prevails. The only exception is ovarian teratoma, which is only associated with wAIHA.

Autoimmune Hemolytic Anemia in Immune Diseases

Autoimmune Hemolytic Anemia in Systemic Lupus Erythematosus and Primary Antiphospholipid Syndrome

The prevalence of AIHA in patients with SLE is 7.5% (average of seven studies; range: 5.2% to 12.5%). AIHA may occur at any time during the course of SLE, but two-thirds of cases of AIHA occur at diagnosis or soon thereafter. Almost half of the patients are already taking steroids. Most patients are women and have wAIHA. Evans syndrome is common. Compared with SLE patients without AIHA, those with AIHA are younger; have a higher prevalence of thrombocytopenia, APAs, renal disease, serositis, and central nervous system involvement; and have a higher risk of venous thrombosis.[40]

The prevalence of AIHA in primary antiphospholipid syndrome (PAPS) is about 10%. AIHA precedes PAPS in 25% of cases, but in others occurred after a median time of 4.4 years after the diagnosis of PAPS. Patients with PAPS and AIHA have an increased risk for the development of SLE.[41]

Autoimmune Hemolytic Anemia in Inflammatory Bowel Disease

In the only larger study, the prevalence of AIHA in ulcerative colitis was 1.7%.[42] The mean time from diagnosis of colitis to AIHA was 17 months. Three-quarters of these patients had total colitis. AIHA may also be associated with Crohn disease, but the prevalence is lower than in ulcerative colitis.

Autoimmune Hemolytic Anemia in Other Immune Diseases

A few or single cases of an association of wAIHA with Sjögren syndrome, dermatomyositis, biliary cirrhosis, Graves disease, Churg-Strauss syndrome, crescentic glomerulonephritis, polymyalgia rheumatica, scleroderma, autoimmune pancreatitis, and cAIHA with rheumatoid arthritis have been reported. A high prevalence of AIHA was found in small children with giant-cell hepatitis.

Autoimmune Hemolytic Anemia in Transplanted Patients

AIHA is a rare but important and dangerous complication of allogeneic hematopoietic stem-cell transplantation (HSCT). Aside from AIHA, causes of hemolytic anemia in transplanted patients may be lymphocyte passenger syndrome and ABO incompatibility. AIHA may be caused by severe immunosuppression by drugs to prevent rejection, graft-versus-host disease (GVHD), viral infections, EBV lymphoproliferative disorder (LPD), or the recurrence of an immune disorder after transplantation (biliary cirrhosis).

The highest rate of AIHA occurred in small children after unrelated cord HSCT for inborn metabolic defects (44%) and in children with severe combined immune deficiency after haploidentical HSCT with T-cell–depleted stem cell grafts.

In adults, the incidence of AIHA ranges from 3.0% to 4.4% after allogeneic HSCT.[43] The median time from HSCT to AIHA is 4 to 10 months. Most patients have wAIHAs. Risk factors for AIHA are unrelated donors, T-cell depletion, and extensive GVHD. In most cases, AIHA occurred in patients in CR of the underlying disease. However, in one study AIHA was associated with a relapse of chronic myeloid leukemia in the majority of patients.

After transplantation of solid organs, the highest risk of AIHA was in patients with pancreatic transplantation. A number of patients with AIHA or cAIHA were observed after liver transplantation, but only a small number were observed after cardiac, lung, intestinal, and renal transplantation. The most likely cause of AIHA in these patients is severe drug-induced immunosuppression.

Autoimmune Hemolytic Anemia in Pregnancy and After Blood Transfusion

Very few cases of AIHA and Evans syndrome—with wAIHAs—occurred during pregnancy. In these patients, there seems to be a higher risk for pre-eclampsia. AIHA responds well to steroids and resolves in most cases after delivery. In two cases, the newborns had mild hemolysis.

Development of RBC autoantibodies is common in multitransfused patients and is associated with the presence of alloantibodies. However, anemia is rare.

Autoimmune Hemolytic Anemia in Malignancies

Autoimmune Hemolytic Anemia in Lymphoproliferative Disorders

AIHA is a typical, relatively common immune-mediated, paraneoplastic syndrome in LPD. It occurs in almost all histologic subtypes of NHL, but there is no correlation between the frequency of lymphoma and the risk of AIHA. AIHA is relatively most common in SMZL and angioimmunoblastic T-cell lymphoma (Table 47.2). In most cases of LPD, wAIHAs is predominant. Most wAIHAs, particularly in CLL, seem to be polyclonal. The proportion of patients with wAIHAs is highest in CLL and Hodgkin lymphoma; in other malignancies, the ratio of wAIHAs to cAIHAs is 2:1. In lymphoplasmacytic lymphoma (LPL), almost all antibodies are clonal cAIHAs.

Autoimmune Hemolytic Anemia as a Risk Factor for Lymphoproliferative Disorder

In various population-based studies, AIHA emerged as a risk factor for subsequent development of diffuse, large B-cell lymphoma, LPL, CLL, monoclonal gammopathy with unknown significance (MGUS), and multiple myeloma. Data regarding the type of AIHA and a possible influence of treatment were not available in these studies. It is uncertain whether autoimmune disorder per se is the causal factor or whether these patients had a clinically silent clonal disorder at the time of AIHA.

TABLE 47.2 Secondary Autoimmune Hemolytic Anemia in Malignancies

Malignancy	Prevalence	wAIHAs	cAIHAs
MGUS	Very low	None	All
All NHL	0.23%–2.6%		
CLL	4.3%–9%	90%	10%
SMZL	10%	2/3	1/3
LPL	3%–5%	None	Most
Angioimmunoblastic T-cell lymphoma	13%	One-third	Two-thirds
Hodgkin lymphoma	0.19%–1.7%	All	None
Ovarian teratoma	Very low	All	None
Solid tumors	Very low	Two-thirds	One-third

cAIHA, Cold autoimmune hemolytic anemia; *CLL,* chronic lymphocytic leukemia; *LPL,* lymphoplasmacytic lymphoma; *MGUS,* monoclonal gammopathy with unknown significance; *NHL,* non-Hodgkin's lymphoma; *SMZL,* splenic marginal zone lymphoma; *wAIHA,* warm autoimmune hemolytic anemia.

Autoimmune Hemolytic Anemia in Chronic Lymphocytic Leukemia

The prevalence of AIHA is highest in CLL, ranging from 4.3% to 9%. The prevalence is highest in poor-risk patients (Binet stage B or C, increased ZAP70 expression, unmutated IgVH status, and CD38 positivity) and patients who had already been treated. However, AIHA may also occur in very early stages of CLL, including B-cell monoclonal lymphocytosis. In a large group of non-treated CLL patients, the prevalence of positive DAT result (with or without anemia) was 14%.[44] Most CLL patients with AIHA are men. The vast majority of patients have (presumably) polyclonal wAIHAs, but in all studies, there is small number of cases with cAIHA (specificity anti-I), often with IgM paraproteinemia.

Autoimmune Hemolytic Anemia in Monoclonal Gammopathy With Unknown Significance and Lymphoplasmacytic Lymphoma

The clinical picture of primary chronic CAD suggests the presence of "idiopathic," or primary cAIHAs, but in fact, most of these patients have a clonal disease with either only clonal IgMk (IgM-MGUS) or LPL with IgM paraproteinemia, MYD88 mutation and bone marrow infiltration (or Waldenström macroglobulinemia). Traditionally, the latter category would be classified as secondary AIHA (CAS). More than 90% of patients with CAD have a monoclonal IgMκ; 7% had IgG or IgA monoclonal immune globulin with λ chains. The course of CAD is usually indolent. Fewer than half of patients require transfusions and the risk for progression to highly malignant lymphomas is small.

Autoimmune Hemolytic Anemia in Other Lymphoproliferative Diseases and Myeloma

The prevalence of AIHA is low in NHL, ranging from 0.23% to 2.6%. AIHA has been described in all histologic subtypes of NHL. Based on the prevalence of NHL, the association with AIHA is highest with SMZL, LPL, angioimmunoblastic T-cell lymphoma, and γ heavy-chain disease. The antibody may be either a warm (two-thirds) or a cold (one-third) antibody. In NHL, there seems to be a relatively frequent association of AIHA with LA, C1-esterase deficiency, or essential cryoglobulinemia.

A number of predominant wAIHAs have been described in IgG and IgA myelomas.

Autoimmune Hemolytic Anemia in Myeloid Disorders

Generally, AIHA is rare in patients with myeloid malignancies. A number of cases have been reported in myelodysplastic syndromes, particularly chronic myelomonocytic leukemia. Very few cases were described in acute myelogenous and lymphoblastic leukemia, myelofibrosis, and polycythemia.

Autoimmune Hemolytic Anemia in Solid Tumors

A special, rare, but highly interesting cause of wAIHA is an ovarian dermoid cyst. These patients respond very poorly to drug therapies, but the AIHA resolves completely and the DAT result becomes negative a few weeks after ovariectomy. The same behavior has been described in microcystic adenoma of the pancreas and dermoid cyst of the mesentery, both associated with AIHA.

AIHA is rarely but definitely associated with solid tumors. It is a very rare complication of lung, renal cell, and ovarian cancer. In some cases of renal-cell cancer, AIHA resolved after curative surgery.

Infection-Related Autoimmune Hemolytic Anemia

In immunocompetent patients, AIHA may occur after viral, bacterial, or parasitic infections (Table 47.3). Virus-associated AIHA occurs mostly in newborns and children; bacterial AIHA occurs more often in adults. The onset of AIHA occurs shortly after signs of infection, but sometimes after a latency time up to weeks. After some specific infections, patients may preferentially develop a warm or a cold antibody (sometimes with specific targets such as I, i, P, or Pr antigen. In almost all instances beside the dominant antibody (cold or warm), a few cases exist of another antibody (see Table 47.3). Of particular interest is varicella-zoster, virus-associated, and rubella-associated cAIHAs, because the cold antibody is mostly directed to the Pr antigen and the AIHA is clinically severe. In *Mycoplasma*-associated AIHA, the antibody target is almost always "I." After *Mycoplasma* infection, the DAT result is positive in 50% to 60% of cases, but anemia is rare. In some specific infections, the antibody was a DL antibody, but in a large study most DL antibodies were found after unspecific respiratory infections.[18] In many cases, the course of AIHA is short, uncomplicated, and self-limited, but some cases with a severe, even fatal, course, particularly in patients with Pr antibodies and in *Mycoplasma*-associated AIHA, have been reported. In AIHA associated with bacterial infections or in leishmaniasis, treatment of the infection seemed to be beneficial.

AIHA has been described in a few cases of acute hepatitis A, B, C, or E and in a number of cases of untreated chronic hepatitis C. However, in a large study, an increased prevalence of AIHA has only been found in interferon (IFN)-treated hepatitis C patients.[45]

Anecdotal reports have described patients in whom wAIHAs were associated with measles, *Chlamydia pneumoniae*, or miliary tuberculosis and cAIHAs with adenovirus, measles, leptospiral pneumonia, *Escherichia coli* infection (all anti-I), pneumococcal pneumonia (anti-Pr), *Haemophilus influenzae* (DL), babesiosis, or *Bartonella henselae* (DAT negative).

Some cases of AIHA have been described after vaccination against hepatitis B, influenza (MF59 adjuvanted), diphtheria–tetanus–pertussis, or rubella. Such associations could not be confirmed in systematic studies.

Recently, both warm and cold autoantibody associated AIHA has been reported in patients with SARS-Cov-2.[46]

Drug-Induced Autoimmune Hemolytic Anemia

Historically, methyldopa, a antihypertensive drug, was the first known drug to induce AIHA. The prevalence of methyldopa-induced AIHA is 1% with 10% to 20% DAT-positive patients without anemia, indicating that DAT positivity is not always followed by overt disease. Currently, IFN-α and purine nucleoside analogues are the most common causes of drug-induced AIHA (Table 47.4). The diagnosis of drug-induced AIHA in a patient with AIHA after drug exposure can only be made if the *indirect* DAT result is positive and the RBC eluate contains an RBC antibody. Such tests have not been performed in all patients in whom drug-induced AIHA was claimed.

The temporal relationship between drug exposure and AIHA is complex. In some instances, AIHA may occur after long-term exposure to a drug (IFN or targeted antibodies). In AIHA caused by purine analogues, AIHA occurs typically after a few cycles of therapy of CLL and is probably dose related (lower incidence and severity at reduced doses of fludarabine). Chlorambucil is said to induce AIHA, particularly after the end of treatment. This has not been found in all studies.

Interferon-induced AIHA has been described in various diseases (particularly hepatitis C and malignant diseases). It is caused by wAIHAs, occurs usually after long exposure to the drug, and disappears spontaneously after cessation of the drug within weeks. AIHA induced by purine analogues (fludarabine, cladribine) occurs mostly during or immediately after the end of drug treatment, but the onset is delayed in some cases. The antibodies are warm or mixed antibodies. This complication occurs predominantly in patients with CLL but seems to be very rare in lymphoma patients treated with these drugs. The incidence of AIHA in patients with CLL after fludarabine or cladribine monotherapy ranges from 2% to 11%. When fludarabine is combined with cyclophosphamide (and rituximab), AIHA is less frequent and probably less severe, but this may be attributable to the lower fludarabine dose in these protocols. Patients with a positive DAT result before treatment have a higher risk of purine analogue-induced AIHA. With steroids alone, about half of the patients achieve

TABLE 47.4 **Drug-Induced Autoimmune Hemolytic Anemia**

Drug	Risk Factors	AIHA Onset	Type of AIHA	Response to Treatment	Diseases Treated

a lasting CR. So far no cases of AIHA have been reported after treatment of CLL with bendamustine.

An interesting and as yet unexplained phenomenon is the fact that some patients with CLL-associated AIHA may achieve remissions after fludarabine or cladribine treatment. However, it is general practice to avoid purine analogues in patients with AIHA. Other drugs that have been associated with wAIHAs (in single case reports) were IFN-β, the monoclonal anti-CD11 antibody efalizumab, and the recently developed checkpoint inhibitors, namely anti-CTLA4 and anti-PD1/PD-L1 antibodies, and lenalidomide.

A peculiar type of cAIHA has been described in some patients with paroxysmal nocturnal hemoglobinuria who had been treated with the anti-C5 antibody ecuzulimab. These patients had an incomplete response to ecuzulimab. The RBCs of these patients accumulate C3d on their surfaces.

Autoimmune Hemolytic Anemia in Immune Deficiency States

AIHA is one of the classical complications of CVID. The prevalence of AIHA was 4% to 5.5% in large studies. AIHA preceded the diagnosis of CVID in more than half of the cases (median time from diagnosis of AIHA to CVID: 5.5 years). Evans syndrome is common.

AIHA (often combined with thrombocytopenia) occurs in 23% to 51% of patients with ALPS. The diagnosis of ALPS is made by the demonstration of a high number of circulating TCRαβ$^+$ double-negative (CD4$^-$ CD8$^-$) T lymphocytes. The basic defect of ALPS is a disturbance of apoptosis.[38]

AIHA is also common in deficiency of purine nucleoside phosphorylase (a T-cell deficiency with almost normal B cells). At least 15% of patients with Wiskott-Aldrich syndrome have AIHA. AIHA occurs before the age of 5 years and is associated with high serum IgM levels. These patients are candidates for allogeneic stem cell transplantation.

DIFFERENTIAL DIAGNOSIS

In patients with DAT-positive hemolytic anemia, the distinction from drug-dependent immune hemolytic anemia is important. In recipients of ABO- or D-incompatible allografts, anti-RBC antibodies are probably produced by immunocompetent memory B cells from the donor. This so-called *passenger lymphocyte syndrome* (PLS) is frequent in heart and lung transplantation (≤68%). A difficult problem is differential diagnosis of DAT-negative AIHA or Evans syndrome. In younger patients with isolated hemolytic anemia with or without symptoms, hereditary diseases such as hereditary spherocytosis, sickle cell anemia, and thalassemia must be considered. Family history and RBC morphology are most helpful in these cases. In patients with drug-induced hemolytic anemia, non-immune hemolysis caused by glucose-6-phosphate-dehydrogenase deficiency should be considered. Babesiosis or other infections may cause non-immune hemolytic anemia. In severely ill patients with hemolytic anemia and thrombocytopenia, idiopathic or cancer-related thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, or disseminated intravascular coagulation should prompt a search for schistocytes in the blood smear.

Paroxysmal nocturnal hemoglobinuria is diagnosed by a deficiency of glycosylphosphatidylinositol anchor proteins on the cell surface caused by a mutation of the *PIG-A* gene. Type II mixed cryoglobulinemia is a condition caused by a monoclonal IgM autoantibody with anti-IgG activity and rheumatoid factor properties frequently associated with hepatitis C. The clinical picture is characterized by a systemic vasculitis syndrome but not by anemia.

TREATMENT

Recommendations for therapy are frequently based on retrospective analyses with small numbers of patients, registries, or expert experience. A few randomized studies have been performed. However, successful phase I and II studies with novel drugs have introduced additional options. The treatment recommendations in this chapter are largely based on published guidelines and the First International Consensus.[8,11,36,47,48]

Goals of Treatment

As in all diseases, the goal of treatment of AIHA is the achievement of a complete clinical and laboratory sustained remission without any residual signs of the disease. Such results can be obtained not only in primary AIHA, but also in a substantial number of secondary cases when the underlying disease disappears spontaneously (infection), when the causative drug is withdrawn, or after (curative) treatment (surgery or chemoimmunotherapy) of an underlying malignancy. In most patients with primary wAIHAs, the expectations for success must be tempered. Therefore, a practical goal is the achievement of a good clinical response with freedom from symptoms in the absence of side effects of treatment. Remission of AIHA after treatment is often defined by laboratory values, but there is no consensus on the definition of CR or partial remission (PR) regarding Hb concentration.[49] Formally, one could define CR as absence of transfusion requirement, a normal Hb value (according to the age and sex of the patient), and absence of signs of hemolysis (normal reticulocyte counts, haptoglobin, and LDH; negative DAT result). Such CR is sometimes seen in secondary AIHA. In primary AIHA, CR is often defined as Hb above 11.0 g/dL without sign of hemolysis, but the DAT result may remain positive. A minimal requirement for PR is the absence of transfusion requirement and a satisfactory clinical condition (usually Hb >9 to 10 g/dL). Thus, in AIHA, the treatment goals must be defined individually and tailored to the patient's needs.[50] Asymptomatic patients with mild anemia (Hb > 10 g/dL) may even be monitored without immediate treatment.

Blood Transfusions

Blood transfusions may be necessary for emergency treatment of AIHA. The problem is to find well-matched RBC concentrates. In critical cases, transfusions should not be avoided or delayed because of uncertainty in matching (see box on Transfusion Therapy in Selected Patients With Severe Autoimmune Hemolytic Anemia). The decision is made on an individual basis depending on the speed of development and severity of anemia, the type and cause of hemolytic anemia (the highest acute death rates were observed in patients with fludarabine-associated AIHA, IgM wAIHAs, and DL antibodies), and the age and clinical condition of the patient. Because the antibody in wAIHAs is directed against blood group antigens, no truly matched blood transfusions are possible, but RBCs can be safely given if alloantibodies are excluded.[3] However, some precautions have to be taken. In patients without a history of previous transfusions or pregnancy the risk of alloantibodies is low, allowing for transfusion of only ABO- and RhD-matched RBCs. In all other patients, extended phenotyping with respect to Rh subgroups (C, c, E, e), Kell, Kidd, and S/s using monoclonal IgM antibodies should be performed for selection of compatible RBC concentrates. Warm autoadsorption or allogeneic adsorption procedures for detection of alloantibodies may be used in exceptional cases. In patients with cAIHAs, transfused blood must be prewarmed using commercial warming coils. In all instances, an important precaution is a biologic in vivo compatibility test, which includes rapid infusion of 20 mL of blood; 20 minutes of observation; and, if there is no reaction, further transfusion at usual speed.

TRANSFUSION THERAPY IN SELECTED PATIENTS WITH SEVERE AUTOIMMUNE HEMOLYTIC ANEMIA

Immediate blood transfusion should not be withheld from patients with severe anemia. Small amounts of red blood cells may be lifesaving in patients with acute cardiac or cerebral dysfunction caused by anemia. However, precautions have to be taken to avoid transfusion reactions. This requires close cooperation between clinicians and the blood bank. The exclusion of alloantibodies is most important. Patients with a low risk for severe reactions caused by an alloantibody are those without a history of previous transfusions or pregnancy. In high-risk patients, extended RBC phenotyping should be performed for selection of compatible RBC concentrates. In all instances, a biologic in vivo compatibility test has to be performed at the beginning of the transfusion.

For patients with warm or cold AIHA with an Hb level greater than 10 g/dL, an inadequate reticulocytosis (which can be assessed by means of the bone marrow reticulocytes index), and the transient (wAIHA) or sometimes long-term (CAD) use of recombinant erythropoietin (RhEpo) can be helpful in about 70% of patients and can decrease transfusion-dependency.[51]

Treatment of Primary Warm Antibody Hemolytic Anemia

First-Line Treatment With Steroids

Newly diagnosed severe wAIHAs should be treated immediately with glucocorticoids (steroids) (Fig. 47.6 and Table 47.5). Therapy starts with an initial dose of 1 mg/kg/day of predniso(lo)ne orally or an equivalent dose of methylprednisone intravenously. It is recommended to continue with this dose until a hematocrit of greater than 30% or a Hb level greater than 10 g/dL is achieved. CR or PR is obtained in approximately 80% of patients. Failure to achieve this goal after 3 weeks should result in a switch to second-line therapy. In responding patients, prednisone dose is gradually reduced to 20 to 30 mg/day within a few weeks. Subsequently, the dose is tapered slowly by 2.5 to 5 mg/day per month guided by Hb and reticulocyte counts. If the patient is still in remission after 3 to 4 months at a dose of 5 mg/day, withdrawal of steroids can be attempted. The exact rate of patients remaining in CR after the end of steroid therapy is not known but is estimated to be around 20% to 40%.[52] Most responders require maintenance steroids to keep the Hb above 9 to 10 g/dL. About 40% to 50% of patients need 15 mg/day or less prednisone (regarded as the highest tolerable dose for long-term treatment). However, 15% to 20% need higher maintenance prednisone doses. Two prospective randomized studies combining prednisone with rituximab have shown higher response rates at 12 months (75% vs. 31% to 36%) and a longer relapse-free survival (70% vs. 45% at 3 years).[53,54] This combination provides a good alternative to initial steroid monotherapy, particularly if the goal is to spare steroids as for elderly patients and/or patients with comorbidities.

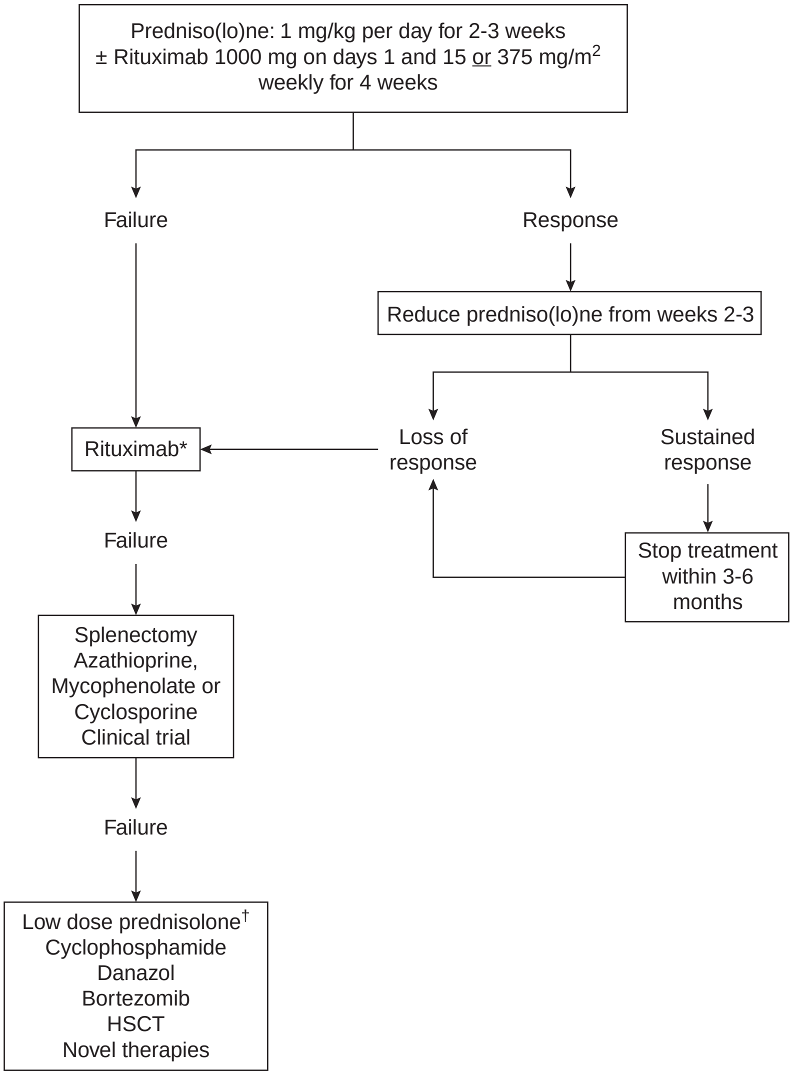
Therapeutic management of steroid treatment should include blood glucose monitoring, prophylaxis against osteoporosis (commence early), supplementation with folic acid, and thromboprophylaxis treatment in selected cases. When rituximab and corticosteroids are combined, a prophylaxis towards *Pneumocystis jirovecii* pneumonia is strongly advised.

Great concerns are osteoporosis, osteonecrosis, and bone fracture particularly of the lumbar spine. About 30% to 50% of patients on long-term steroid treatment experience fractures. The highest loss of bone density occurs early, even at smaller steroid doses, and the risk of fracture increases by 75% during the first months of treatment.

Thus, patients on steroid therapy should receive bisphosphonates, vitamin D, and calcium from the beginning. Folic acid is also recommended. Steroid-induced diabetes is a major risk factor for treatment-related deaths from infections. Although heparin treatment is not recommended for all patients, the possibility of pulmonary embolism must be considered, particularly in patients with AIHA and LA or recurrent AIHA after splenectomy. Previous studies have also found a beneficial effect of standard heparin in AIHA.[10,36]

Second-Line Treatment

Second-line treatment is considered in patients (1) refractory to initial steroids as defined earlier, (2) in need of a maintenance dose of more than 15 mg/day of prednisone (absolute indications), or (3) who need between 15 mg/day and 0.1 mg/kg/day (relative indication; Fig. 47.6). Patients with prednisone requirement of 0.1 mg/kg/day



Predniso(lo)ne: 1 mg/kg per day for 2-3 weeks
± Rituximab 1000 mg on days 1 and 15 or 375 mg/m2 weekly for 4 weeks
Failure
Response
Reduce predniso(lo)ne from weeks 2-3
Loss of response
Sustained response
Rituximab*
Stop treatment within 3-6 months
Failure
Splenectomy
Azathioprine, Mycophenolate or Cyclosporine
Clinical trial
Failure
Low dose prednisolone†
Cyclophosphamide
Danazol
Bortezomib
HSCT
Novel therapies

*If rituximab given first line, re-treatment may be considered if a sustained response was achieved. Otherwise, move to third-line options.

† Prednisolone 10 mg daily ± a steroid-sparing agent
HSCT; haematopoietic stem cell transplantation

Figure 47.6 PROPOSED ALGORITHM FOR THE TREATMENT OF PRIMARY WARM ANTIBODY AUTOIMMUNE HEMOLYTIC ANEMIA IN ADULTS. *IV*, Intravenous; *IVIg*, intravenous immunoglobulin; *PDN*, prednisone. *(Modified from Lechner K, Jäger U. How I treat autoimmune haemolytic anemias in adults. Blood. 2010;116:1831.)*

or less are potential candidates for long-term, low-dose prednisone. Patients refractory to steroid treatment should be re-evaluated for underlying diseases or warm IgM antibodies (Table 47.6).

Rituximab

Rituximab off-label is currently the best available drug option for second-line treatment).[55–57] It can be given either at a standard induction dose of 375 mg/m^2 intravenously on days 1, 8, 15, and 22 or at a fixed dose of 1000 mg 2 weeks apart. In a meta-analysis of 21 studies, the ORR for wAIHAs after rituximab was 79% (67% for primary and 72% for secondary).[57] The CR rate was 42% (32% primary and 46% secondary). The median time to response was 3 to 6 weeks with the highest CR rate after 2 to 4 months. Approximately half of the patients had concomitant steroids. Rituximab therapy results in good long-term response rates with only 30% of initial responders relapsing at 3 years. Low-dose rituximab at 100 mg/m^2 for 4 consecutive weeks also produced high response rates.[58,59]

Patients taking steroids before initiation of rituximab should continue on a low dose of steroids until response to the CD20 antibody. Predictors of long-term response are an achievement of a CR, conversion to a negative DAT result, and previous splenectomy.

Re-treatment of relapsing patients with rituximab is feasible and results in similar response rates. Rituximab has been given to children without apparent safety problems.

The caveats of rituximab therapy are that the drug is not licensed for the indication and its well-known side effects including infectious complications also apply for AIHA patients. Whenever possible, in a non-splenectomized patient, anti-pneumococcal vaccination should be performed at least 2 weeks before the first administration of rituximab.

Third-Line Treatment

Azathioprine

Efficacy has been reported in small series with response rates of 56% to 71%.[10] Azathioprine is dosed at 2 to 2.5 mg/kg/day (if thiopurine methyltransferase testing is available) or at a starting dose of 50 mg daily.

TABLE 47.5 Treatment Options for Primary and Secondary Warm Autoimmune Hemolytic Anemia and Cold Autoimmune Hemolytic Anemia

Disease or Condition	First Line	Second Line	Beyond Second Line	Last Resort
Primary AIHA	Steroids (+ rituximab)	Splenectomy Rituximab	Azathioprine, MMF, cyclosporine, cyclophosphamide	High-dose cyclophosphamide, bortezomib, alemtuzumab
B- and T-cell NHL	Steroids	Chemotherapy ± rituximab (splenectomy in SMZL)	Other anti-CD20 antibodies, ibrutinib	
Hodgkin lymphoma	Steroids	Chemotherapy	Rituximab if HL is in remission	
Solid tumors	Steroids Surgery			
Ovarian dermoid cyst	Ovariectomy			
SLE	Steroids	Rituximab	MMF Azathioprine	Autologous SCT
Ulcerative colitis	Steroids	Azathioprine		Total colectomy
CVID	Steroids + IgG replacement			
ALPS	Steroids	MMF	Sirolimus	
Wiskott-Aldrich syndrome	Steroids	Allogeneic SCT		
Allogeneic SCT	Steroids	Rituximab[a]	Splenectomy T-cell infusion	
Organ transplantation	Reduction of immunosuppression, steroids			
Drug induced	Withdrawal	Steroids		
Primary CAD	Protection from cold exposure	Rituximab	Bendamustine + rituximab	Sutimlimab, ecuzulimab[b] bortezomib[b]
PCH	Supportive treatment (postinfectious)	Rituximab[a] (chronic)		

[a] Early second-line treatment because of known poor response to steroids.
[b] Off-label use in single cases.
AIHA, Autoimmune hemolytic anemia; *ALPD*, autoimmune lymphoproliferative disorders; *ALPS*, autoimmune lymphoproliferative syndrome; *CAD*, cold agglutinin disease; *CVID*, common variable immune deficiency; *IgG*, immunoglobulin G; *MMF*, mycophenolate mofetil; *NHL*, non-Hodgkin lymphoma; *PCH*, paroxysmal cold hemoglobinuria; *SCT*, stem cell transplantation; *SLE*, systemic lupus erythematosus; *SMZL*, splenic marginal zone lymphoma.

Cyclosporine

At an initial dose of 2.5 mg/kg twice daily the response rate was 58% in all AIHA types.[60] Repeated cycles of high-dose cyclophosphamide (50 mg/kg/day for 4 days) remain an option in selected, highly refractory patients. In a pilot study, six out of nine patients received a CR with a median duration of 15 months or more.

Mycophenolate mofetil

At a starting dose of 500 mg twice daily with escalation to 1 g, varying response rates from 25% to 100% were observed in rather small series.[61]

Splenectomy

Splenectomy has been a good second-line option before the establishment of rituximab. CR or PR is achieved in two-thirds of patients (38% to 82%), depending on the percentage of secondary cases. In addition, there is good evidence that a substantial number of patients will remain in remission without the need for medical intervention for years. In the initial series by Chertkow and Dacie,[62] only 2 out of 28 patients were in remission for more than 5 years, but 6 patients remained in a stable PR for up to 7 years. In 52 splenectomized patients (percentage of primary AIHA unknown), Coon[63] found that 63% had a hematocrit of 30% or greater without steroids after a mean follow-up of 33 months, and 21% had a hematocrit of 30% or greater with a prednisone requirement of 15 mg/day or less after a mean follow-up of 73 months. In a study by Allgood and Chaplin,[64] 44% of patients were in CR after more than 1 year after splenectomy.

Splenectomy can safely be performed laparoscopically in almost all patients with primary AIHA with normal-sized spleens. The mortality rate of laparoscopic splenectomy was 0.5% in a large national study.

There is a lifelong increased risk of infections and venous thrombosis and a very small risk of pulmonary hypertension. The most serious, often fatal, but rare infectious complication is overwhelming pneumococcal septicemia. The risk of infections is highest shortly after splenectomy and decreases after 2 years. Although fatal postsplenectomy infections seem to be less common in recent years, it is mandatory to take all measures to reduce this risk. Vaccination for pneumococci, meningococci, and *Haemophilus influenzae* should be done before splenectomy. Pneumococcal vaccination should be repeated regularly. Long-term antibiotic prophylaxis is probably not required in adults, but patients should be informed about this risk and should take antibiotics immediately in case of unexplained fever. Risk in children may be reduced by subtotal splenectomy.

Treatment Options Beyond Third Line.

The proteasome inhibitor *bortezomib*, given in combination with dexamethasone, induced responses in children and adult patients with refractory wAIHA, although numbers are small.[65,66]

TABLE 47.6 **Second-Line Treatment Options After Steroids**

Treatment	Dosing and Application	Side Effects	Precautions
Rituximab	375 mg/m^2 on days 1, 8, 15, and 22 IV or 1000 mg fixed dose 2 weeks apart	Infusional reactions Serum sickness disease Late-onset neutropenia Infections	Premedication with antihistamines (and steroids) Consider prophylaxis against pneumocystis jiroveci pneumonia
Splenectomy (acute)	Preferentially laparoscopic	Infections, thrombosis	Postoperative thromboprophylaxis
Splenectomy (long term)	—	Infections Venous thrombosis	Vaccination, patient information
Danazol	200–400/day PO	Hepatotoxicity, hirsutism	None
Cyclophosphamide	PO or IV Dose adjusted to neutrophil count	Neutropenia Mutagenesis	Neutrophil count monitoring, bladder protection after high doses
Azathioprine	2.0–3 mg/kg/day PO Dose adjusted to neutrophil count	Neutropenia	Neutrophil count monitoring; avoid interaction with other drugs (e.g., allopurinol)
MMF	1–2 × 1 g/day PO	Gastrointestinal	
Cyclosporine	PO Dose adjusted to blood levels of CyA Target level, 200–400 ng/mL	Nephrotoxicity Gum hyperplasia hypertension	Monitoring of CyA levels and creatinine
Alemtuzumab	SC (variable doses)	Neutropenia	Anti-infectious prophylaxis
Complement inhibition with sutimlimab (CAD)	60 mg/kg after test dose of 10 mg/kg	Infections	Vaccination

CyA, Cyclosporine A; *IV*, intravenous; *MMF*, mycophenolate mofetil; *PO*, oral; *SC*, subcutaneous.

Danazol has shown some activity but seems to be less effective in refractory wAIHA.[67,68]

Response to *intravenous immunoglobulin* was reported in 12 of 37 patients at doses of 0.4 to 0.5 hg/kg in one retrospective study, but robust evidence of their efficacy in this setting are lacking and their use may enhance the risk of thrombosis.[69]

The results of *autologous stem-cell transplantation* were disappointing, but allogeneic transplantation may be used as a last-resort treatment in patients with Evans syndrome.

High-dose methyl-prednisolone, emergency splenectomy, partial splenic embolization, or plasma exchange may be used in emergency situations, but data are limited.

Novel agents in clinical studies. The tyrosine kinase inhibitors fostamatinib (syk) and INCB050465(PI-3kinase) have shown promising activity and are investigated in clinical studies.[36] Therapeutic antibodies against the neonatal FC-receptor (e.g., orilanolimab) showed promising effects.

With the advent of more novel agents, patients in need for third-line treatment should be referred to clinical studies.

Treatment of Secondary Warm Autoimmune Hemolytic Anemia

In secondary wAIHA, the treatment goal depends on the type and severity of the underlying disease. The treatment goal may vary from palliative treatment of AIHA, to cure by eradication of the underlying disease. Preferred treatment options are listed in Table 47.6.

Warm Autoimmune Hemolytic Anemia Associated With Systemic Lupus Erythematosus

Given its activity in both diseases, rituximab seems to be a reasonable option.[70] Increased side effects should be considered in patients with previous or concomitant immunosuppressive therapies.

Steroids used at a similar dosage as in primary wAIHAs induce high response rates. Concomitant treatment with hydroxychloroquine is advised, although its efficacy for AIHA as a steroid-sparing agent has not been proven. Maintenance treatment with azathioprine, cyclophosphamide may be required. Mycophenolate mofetil is an alternative. Splenectomy should be avoided due to a high infection and thrombosis rate especially if antiphospholipid antibodies are present.

Warm Autoimmune Hemolytic Anemia Associated With Chronic Lymphocytic Leukemia

In previously untreated CLL with isolated DAT-positive anemia but no other treatment indication, treatment with prednisone as in primary wAIHAs is the first choice.[71,72] Rituximab monotherapy has response rates of up to 71% but responses may not be sustained.[73,74] Combination of rituximab in combination with cyclophosphamide and dexamethasone produces response rates of over 80%[73] Cyclosporine also has good activity. In refractory AIHA or in AIHA with advanced or progressive CLL, treatment of the underlying disease with a rituximab-containing regimen—according to International

Workshop on Chronic Lymphocytic Leukemia guidelines—is recommended.[74] In general, fludarabine-containing regimens should be used with caution in the presence of a positive DAT result or overt AIHA. In this case, bendamustine with (or without) rituximab is a good alternative. There is increasing evidence that obinutuzumab, ibrutinib, or venetoclax are effective even in refractory wAIHA associated with CLL.[36,75] On the other hand, immune cytopenias may also occur during inhibitor treatment.[76]

Warm Autoimmune Hemolytic Anemia in Other Non-Hodgkin Lymphomas

AIHA in NHLs does not respond well to steroids in general and splenectomy is only effective in SMZLs. Sustained responses in most other lymphoma subtypes have been obtained with lymphoma-specific treatment with or without rituximab.

Drug-Related Warm Autoimmune Hemolytic Anemia

Cessation of the drug may be effective in many cases and further use of the drug should be avoided. Fludarabine-induced AIHA may be life threatening but responds to steroid therapy.

Treatment of Warm Autoimmune Hemolytic Anemia in Congenital and Acquired Immune Deficiency States and Special Serologic Types

The treatment of wAIHAs in patients with CVID is very similar to that of those with primary wAIHA. Additional regular prophylactic treatment with subcutaneous Ig reduces the risk of infection especially if rituximab is considered. Splenectomy is effective, but the risk of serious infections is increased in this setting.

In ALPS, treatment should be started with steroids and then switched to MMF, but sirolimus has the highest efficacy in improving not only AIHA but also lymphadenopathy. Both rituximab and splenectomy should be avoided as the risk of severe infections is much higher in this context. AIHA associated with IgM hypergammaglobulinemia in Wiskott-Aldrich syndrome is an indication for allogeneic stem cell transplantation.

Patients with AIHA after allogeneic stem cell transplantation respond poorly to steroids but often do respond to rituximab. An early switch to rituximab may be reasonable in these patients. AIHA in drug-related severely immunosuppressed patients after transplantation of solid organs responds best to reduction of immune suppression. Patients with IgM wAIHAs respond poorly to steroids. These patients are candidates for early rituximab treatment. The same is true for chronic AIHA caused by DL antibodies.

Treatment of Cold Autoimmune Hemolytic Anemia

Primary Chronic Cold Agglutinin Disease

Primary CAD is defined as a cAIHAs in patients with IgM-MGUS or lymphoma without overt clinical signs but with bone marrow infiltration. All patients should be advised to avoid cold exposure. Drug treatment is required in 30% to 50% of the patients.[77] Watchful waiting is indicated, but thromboprophylaxis is recommended in episodes of exacerbations or risk situations.

First-Line Therapy

Treatment is initiated in symptomatic patients or when Hb levels drop below 10 g/dL (Fig. 47.7). Because IgM-coated RBCs are mainly destroyed in the liver, cAIHA does not respond to splenectomy and responds poorly to steroids. The most effective and best evaluated treatment is rituximab in a standard lymphoma dose. Two studies have provided similar results. In a prospective phase II study, 20 out of 27 patients responded, but most responses (n=19) were partial. The median response duration was 11 months, but most patients responded to retreatment with rituximab. In a meta-analysis, the ORR for rituximab in CAD was 57% with a CR rate of 21%.[57] The Nordic group has reported excellent results for combinations of rituximab with fludarabine, but even better with bendamustine for CAD.[78–80]

Response to rituximab with bendamustine may take time but lasts for years in the majority of patients.

Second-Line Therapy

A combination of rituximab and oral fludarabine induced higher ORRs (76%) with a longer duration (median: 66 months). A prospective trial with single agent bortezomib showed the activity of this drug with 6 of 19 patients responding to a single cycle.[81]

While all previously mentioned treatments intend to eradicate or suppress the causative B-cell clone, complement plays a decisive role in the execution of hemolysis and can also be targeted. Initial studies with the terminal complement inhibitor ecuzulimab showed moderate responses.[82,83] The most striking results have been obtained with the C1s antibody sutimlimab.[84,85] Seven of 10 patients responded an increase in Hb of >2 g/dL. Responses with normalization of bilirubin, reticulocyte counts occurred within a few days, which makes this treatment also attractive for emergency situations. The disadvantage of complement inhibition is that this therapy is symptomatic and needs maintenance or rechallenge.[86] No major infectious complications have been observed in vaccinated patients. Other complement antibodies and inhibitors are being developed.

Emergency Situations and Further Treatment Lines

Blood transfusions may be necessary, particularly during the initial phase of treatment. The use of IVIg or plasma exchange can be considered. Given their efficacy in B-cell malignancies, inhibitors like ibrutinib (*BTK*) or venetoclax (*BCL2*) may not only be effective in secondary cold agglutinin syndrome.

Secondary Cold Agglutinin Syndrome

In cAIHAs associated with lymphomas or solid tumors, treatment of the underlying disease by chemo(immuno)therapy or curative resection results in good responses. Cases of infection-related cAIHAs usually resolve spontaneously, but antibiotic therapy may accelerate the process.

FUTURE DIRECTIONS

Future research should mainly be directed toward generation of better treatment options. The generation of international guidelines is still hampered by the lack of evidence. Every effort should be made to initiate valid comparisons of major treatment options such as steroids, splenectomy, and rituximab, potentially through registries or randomized trials.

Novel therapeutic options may be provided by next-generation anti-CD20 antibodies or antibodies against other targets such as complement factors. Insights into the way T cells drive and control the immune reaction could lead to novel immunotherapeutic approaches. Synthetic peptides modulating Th1 responses via regulatory T cells may be developed into therapeutic tools. Another option would be to target structures on macrophages responsible for RBC destruction (e.g., the CD47–SIRP-α interaction). After years of small studies and case reporting, a number of novel agents are now being studied prospectively in well powered phase II or even randomized phase III trial.

There is hope that novel targeted therapies will replace the current treatment of patients with AIHA.

CHAPTER 48

EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIAS

William C. Mentzer and Stanley L. Schrier†

By definition, extrinsic causes of hemolysis are abnormalities in the environment in which the red blood cells (RBCs), usually normal themselves, circulate. These abnormalities can be acute or chronic in nature. They can arise from congenital lesions but usually result from acquired insults. Inherited anomalies of glucose-6-phosphate dehydrogenase (G6PD) deficiency, which reduces the RBCs' ability to deal with oxidative stressors, can leave RBCs more vulnerable to a variety of environmental insults. Determination of hemolysis with various levels of compensation as the cause of an anemia is accomplished using the approaches described in Chapter 34. Signs of extrinsic hemolysis with minimal or no anemia can be valuable clues to diseases of other organ systems. Among the most important forms of extrinsic hemolytic anemia are those caused by immune mechanisms; these are discussed in Chapter 46.

Extrinsic triggers of red cell destruction can lead to either intravascular or extravascular hemolysis or both. In general, only the most devastating damage leads to direct intravascular destruction. Usually, the initial insult leads to an eventual change in the external portion of the RBC membrane, which causes macrophages to retard, hold, remove, or otherwise modify RBCs. Infection or inflammation can activate these macrophages. Some RBC changes are accompanied by a decrease in RBC deformability, which retards flow and thereby facilitates the action of macrophages on the affected RBC. All of these changes lead to extravascular hemolysis.

FRAGMENTATION HEMOLYSIS: MICROANGIOPATHY

Clinical Manifestations

Patients present with various degrees of hemolytic anemia and compensation, with evidence of RBC fragmentation on smear (Fig. 48.1; see the box on Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias). RBC removal is generally extravascular, with minimal or moderately decreased levels of haptoglobin. If RBC damage is sufficiently severe, signs of intravascular hemolysis may be present. Because of the underlying pathology, some of these syndromes show evidence of platelet removal, leading to thrombocytopenia. Occasionally, the underlying cause produces activation and depletion of procoagulant factors with consequent activation of the fibrinolytic system, consistent with disseminated intravascular coagulation (DIC; see the box on Causes of Red Blood Cell Fragmentation Hemolysis).

DIFFERENTIAL DIAGNOSIS OF EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIAS

There is no simple approach to the differential diagnosis of hemolysis caused by extrinsic nonimmune hemolytic anemia. The physician must pay close attention to the clinical finding. Useful clues come from a determination of whether red blood cell (RBC) breakdown is predominantly extravascular or intravascular, but most important in the analysis is the observation of RBC morphology, which can focus the differential diagnosis. Unhelpful terms such as *aniso* and *poik* should be discarded. RBCs are spherocytic, stomatocytic, fragmented, echinocytic, acanthocytic, spurred, or bite cells, or can be mixtures of these types.

CAUSES OF RED BLOOD CELL FRAGMENTATION HEMOLYSIS

- Damaged microvasculature
- Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS)
- Associated with pregnancy: preeclampsia or eclampsia; hemolysis plus elevated liver enzymes plus low platelets (HELLP syndrome)
- Associated with malignancy, with or without mitomycin C treatment
- Vasculitis: polyarteritis, Wegener granulomatosis, acute glomerulonephritis, or *Rickettsia*-like infections
- Systemic lupus erythematosus
- Abnormalities of renal vasculature: malignant hypertension, acute glomerulonephritis, scleroderma, or allograft rejection with or without cyclosporine treatment
- Disseminated intravascular coagulation
- Malignant hypertension
- Catastrophic antiphospholipid antibody syndrome
- Atrioventricular malformations
- Kasabach-Merritt syndrome
- Hemangioendotheliomas
- Atrioventricular shunts for congenital and acquired conditions (e.g., stents, coils, transjugular intrahepatic portosystemic shunt, Levine shunts)
- Cardiac abnormalities
- Replaced valve, prosthesis, graft, or patch
- Aortic stenosis or regurgitant jets (e.g., in ruptured sinus of Valsalva)
- Drugs: cyclosporine, mitomycin, ticlopidine, clopidogrel, tacrolimus, or cocaine
- Systemic infection: bacterial endocarditis, brucellosis, cytomegalovirus, HIV, ehrlichiosis, Rocky Mountain spotted fever.

HELLP, Hemolysis, elevated liver enzymes, and low platelet count; *HIV*, human immunodeficiency virus.

Pathophysiology

Fragmentation hemolysis occurs when mechanical forces disrupt the physical integrity of the RBC membrane. In vitro shear stresses in excess of 3000 dynes/cm^2 cause RBC fragmentation. For example, in vivo studies in patients with mitral prosthetic regurgitation and hemolysis show high peak shear stresses of 4500 dynes/cm^2, very rapid acceleration or deceleration, or both. Valvular abnormalities or prosthetic vales can thus cause microangiopathic changes.

Research suggests additional mechanisms of producing microangiopathic hemolysis that involve platelets and small vessel thrombi. The platelet-rich, fibrin-poor microvascular thrombi found in many patients with thrombotic thrombocytopenic purpura (TTP) (see Chapter 134) now are thought to be caused by abnormally decreased ADAMTS 13 activity.[1,2] This metalloprotease is responsible for converting the highly thrombogenic ultra-large multimers of von Willebrand factor made by platelets and endothelial cells into the smaller forms normally found in circulation. Mutations in or antibodies against ADAMTS 13 result in unusually large multimers of von Willebrand factor attached to endothelial cell surfaces, where platelets may excessively aggregate, leading to the formation of microvascular thrombi even in the absence of endothelial damage. In the case of disseminated cancer, the cause of microangiopathy may be microvascular tumor emboli.

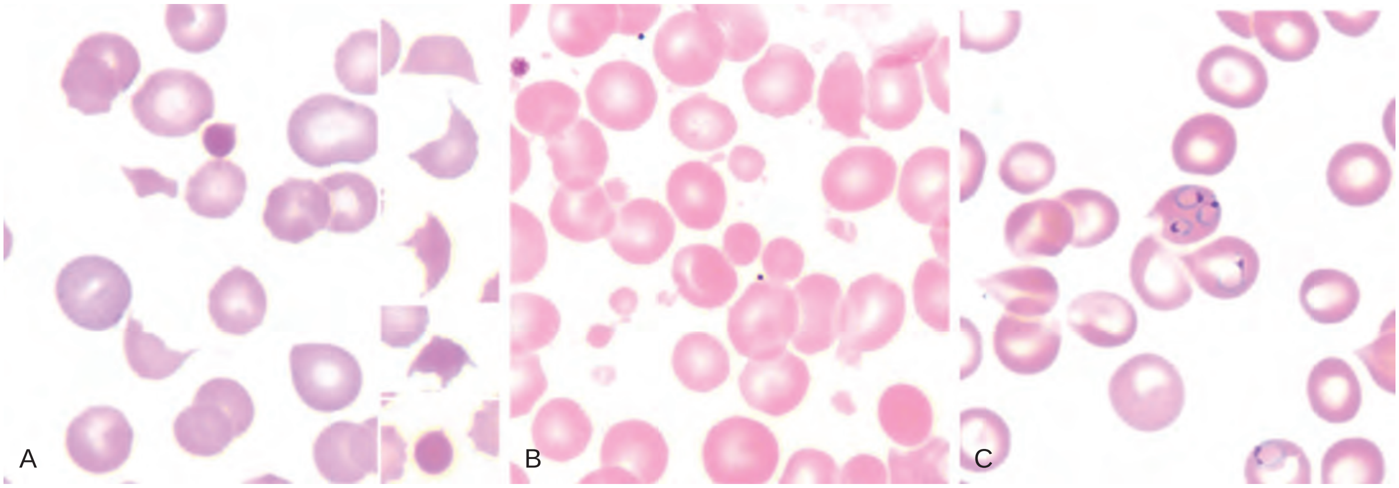

Figure 48.1 PERIPHERAL BLOOD SMEARS FROM EXAMPLES OF EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIA. (A) Microangiopathic hemolytic anemia. Note the schistocytes, fragmented cells, spherocyte, and polychromasia. More examples of damaged red blood cells (RBCs), including classic "helmet cell" *(top)*, are seen to the immediate *right insert*. (B) Thermal injury from a burn. Thermally damaged RBCs form numerous microspherocytes and tiny RBC fragments. (C) Malaria infestation. RBCs containing *Plasmodium falciparum* malaria. Note the high rate of infestation, the presence of only ringed forms, and the multiply infested RBCs *(center)*.

Whatever the mechanism of mechanical trauma, the RBC membrane is viscoelastic and has self-sealing properties (see Chapter 45) so that little hemoglobin leaks out as the cell is being cut. However, prolonged distortion of the membrane produces a plastic change; therefore, the smaller RBC fragments usually do not become microspheres or microdisks but continue to display evidence of the shearing event or distortion in the form of typical irregular shapes. These irregular shapes and the rigidity that they reflect subsequently interfere with the ability of RBCs to fold, elongate, and deform sufficiently to pass through 3-μm capillaries and even smaller slits in the walls of the sinusoids of the reticuloendothelial system. This sequence leads to their destruction.

Differential Diagnosis

Generally, the differential diagnosis of fragmentation hemolysis can be deduced from the clinical findings. The presence of a prosthetic heart valve or a regurgitant jet that fragments or accelerates (i.e., Waring blender syndrome) can be readily discerned.[3] The clinical picture of thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (TTP–HUS) is generally dramatic and acute (see Chapter 134). Atrioventricular malformations may be associated with disseminated intravascular coagulation (DIC) and platelet removal; the diagnosis requires a high index of suspicion and imaging studies. The presence of preeclampsia in a pregnant woman with microangiopathic hemolysis usually is obvious, but hemolysis plus elevated liver enzymes plus low platelet count (HELLP) syndrome is a serious complication of pregnancy that can occur without other signs of preeclampsia or hypertension. This syndrome can produce hepatic rupture, visual failure, DIC, seizures, and congestive heart failure and requires treatment by prompt delivery of the fetus. Cancer can be an underlying cause of microangiopathy. Vessels supplying malignant tumors are thought to be structurally abnormal. They exhibit the same sort of fibrin stranding that produces fragmentation hemolysis in DIC and TTP–HUS.

Continued use of invasive diagnostic and therapeutic procedures with insertion of foreign bodies into the circulation has been complicated by microangiopathic hemolysis. A transjugular intrahepatic portosystemic shunt can cause the syndrome in approximately 10% of patients. The hemolysis usually disappears after 12 to 15 weeks. Similarly, the use of coil embolization to seal off a patent ductus arteriosus may also cause significant hemolytic anemia. Vasculitis has also been implicated as a cause.

Multiple drugs are associated with microangiopathic hemolysis, most commonly quinine.[3,4] A recent review found that in only 22 of 78 drugs reported to produce drug-induced thrombotic microangiopathy was a definite association found.[4] Cyclosporine, tacrolimus, and mitomycin C have been implicated as causing a HUS picture that typically develops within weeks to months of exposure. Total body irradiation and bone marrow transplantation also are associated with microangiopathic hemolysis. Both chemotherapeutic agents and targeted cancer agents, including immunotoxins, monoclonal antibodies, and tyrosine kinase inhibitors, are associated with thrombotic microangiopathy.[5] The thienopyridines ticlodipine and clopidogrel are both capable of producing a significant thrombotic microangiopathy that differs somewhat in presentation. Ticlodipine-associated TTP typically occurs between 2 and 12 weeks after initiation of therapy and presents with severe thrombocytopenia, microangiopathic hemolytic anemia, highly elevated lactate dehydrogenase, and normal renal function and is associated with severe deficiency of plasma ADAMTS13 activity.[6] In contrast, clopidogrel-associated TTP usually presents within 2 weeks of drug initiation and is associated with mild thrombocytopenia, microangiopathic hemolytic anemia, mildly elevated lactate dehydrogenase levels, marked renal insufficiency, and near-normal levels of ADAMTS13 activity. Other reported exposures associated with microangiopathic hemolytic anemia include the use of cocaine and the herb Echinacea. The mechanisms of drug-induced thrombotic microangiopathy are not well understood but include immune-mediated causes (as in the case of quinine) and direct toxicity to the endothelium.[4]

Thrombotic microangiopathic hemolytic anemia can also be the presenting feature of severe, systemic infection, including viral (cytomegalovirus [CMV], HIV), fungal, and bacterial infections.[7] Whether infection "triggers" the development of TTP or instead the presentation remains debatable.

In one large series, 10 of 351 (2.8%) patients diagnosed with TTP were subsequently diagnosed with disseminated malignancy.[8] Symptoms suggesting an underlying malignancy include dyspnea, cough, atypical pain, and poor response to plasma exchange. The diagnosis was made by bone marrow biopsy in six of the 10 patients, and all patients died shortly after the diagnosis of malignancy was made.

A current review highlights four hereditary and four acquired disorders that lead to thrombotic microangiopathy.[2] TTP may be hereditary, due to mutations in ADAMTS13, or acquired, due to autoantibody inhibition of ADAMTS13 activity. In addition, complement mutations causing uncontrolled activation of the alternative pathway, mutations in components of cobalamin metabolism, and mutations in a protein kinase C-associated protein, diacylglycerol kinase, are other hereditary causes of thrombotic microangiopathy. Acquired causes in addition to autoantibodies to ADAMTS13 include shiga toxin (hemolytic uremic syndrome), drug mediated on an immune basis (i.e., quinine), drug mediated on a toxic, dose-related basis (i.e., gemcitabine, cyclosporine), and acquired antibodies to complement factor H.

Therapy

Management is primarily directed toward the underlying disease or event. Compensation of RBC production should be optimized by replacing iron or folic acid if the patient is deficient in these nutrients. Occasionally, removal or repair of a damaged native or prosthetic heart valve is necessary when the hemolysis produces a disabling transfusion requirement. Treatment of TTP with plasma exchange is highly effective in classic TTP with very low ADAMTS13 levels but not indicated in other settings of thrombotic microangiopathy such as cancer where plasma exchange may be ineffective. Where autoantibodies to ADAMTS13 are central to pathogenesis, immunosuppressive treatment with steroids and rituximab is important adjuvant therapy.[9]

OTHER FORMS OF MECHANICAL DAMAGE TO RED BLOOD CELLS

Heat Denaturation

Normal RBCs undergo budding and fragmentation when exposed to a temperature of 49°C (120°F) in vitro (see Fig. 48.1B). In some of the hereditary hemolytic anemias, this process occurs at temperatures as low as 46°C (115°F; see Chapter 45). Under some clinical circumstances, temperatures sufficient to cause heat denaturation of RBCs have been generated. Occasionally, cell warmers used with transfusions in cold agglutinin disease have malfunctioned and cooked the RBCs about to be transfused. In one case, a patient's mother warmed the RBCs with a hot water bottle, reasoning that such cells would cause less vein irritation to her child. Such transfusion was followed by evidence of intravascular and extravascular hemolysis, and the peripheral smear showed RBC budding and fragmentation (Fig. 48.2). Presumably, similar events can lead to hemolysis in patients who have sustained very extensive burns. In patients with heat stroke, the temperature usually is below 42°C (108°F), a temperature at which little RBC denaturation occurs.

Mechanical Trauma

The classic example of RBC damage caused by mechanical trauma is march hemoglobinuria, which occurs in soldiers after a long march, in joggers after running on a hard road, or in karate or conga drumming enthusiasts after practice. Anemia is rare, and reticulocytosis is uncommon. Evidence of typical intravascular RBC destruction is present and is thought to be caused by direct trauma to RBCs in the vessels of the feet or hands. Switching jogging paths or wearing better footwear often relieves the problem. Some cases show evidence of an underlying RBC membrane abnormality. Strenuous exercise may induce oxidant stress, as evidenced by increased levels of malonyldialdehyde, a marker of lipid peroxidation, in marathon runners after a race. Occasionally, malfunction of the cell savers used during abdominal or thoracic surgery mechanically injures RBCs.

Cardiopulmonary Bypass

Postperfusion syndrome occurs in some patients after cardiopulmonary bypass. The syndrome includes acute intravascular hemolysis and leukopenia as part of a febrile, inflammatory clinical picture. Affected patients may develop pulmonary distress and even adult or acute respiratory distress syndrome. Visible hemoglobinemia occurs, with rising plasma hemoglobin levels, and is associated with an increase in lysed RBC ghosts seen in the whole blood and plasma. These ghosts are coated with the complement complex C5bC9 (see Chapter 24). Presumably, the complement pathway is activated as the blood passes through the oxygenator. The reason why complement activation results in lytic attack on RBCs (and granulocytes) is unknown. Free hemoglobin released into the plasma secondary to intravascular hemolysis may contribute to acute kidney injury after cardiopulmonary bypass. Treatment involves knowledge of the process and requisite support until the situation corrects itself.

Osmotic Attack

Abrupt changes in osmolality can cause hemolysis. Freshwater drowning may be associated with so much water in the lungs that the RBCs swell as they undergo an in vivo osmotic fragility test in the pulmonary vasculature. Conversely, saltwater drowning can cause profound dehydration of RBCs, producing a situation analogous to xerocytosis (see Chapter 45). Rarely, acute hemolysis occurs from the mistaken infusion of or exposure to concentrated hypertonic solutions such as those used in hemodialysis. To manage such an event, the physician must recognize its cause, appreciate the shrunken RBCs on a peripheral smear, and restore isotonicity as quickly as possible. In these cases, the use of a hemodialysis device, if available, may be helpful.

Hypersplenism

In all organs of the monocyte–macrophage system (i.e., reticuloendothelial system), blood cells leaving the arterial bed are generally unloaded into channels such that the RBCs must pass through the

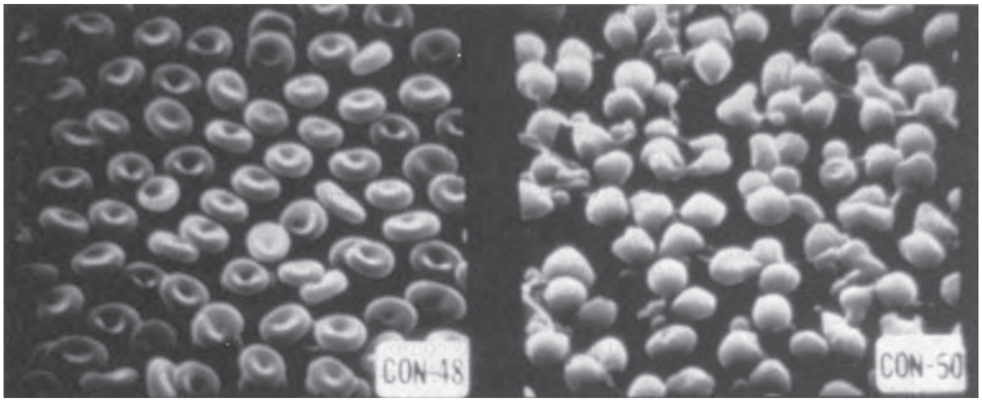

Figure 48.2 MORPHOLOGIC CHANGES ARE PRODUCED BY HEATING NORMAL RED BLOOD CELLS AT THE INDICATED TEMPERATURES. Budding begins abruptly at 50°C (122°F) and eventually leads to spherocytosis.

wall of the sinus to reenter the circulation. The sinusoidal wall in the spleen has slits 2 to 3 μm long and usually is endothelialized on one side and has a macrophagic lining on the other side. The normal human adult RBC is a discocyte with a surface area 40% larger than a sphere of that volume (see Chapter 33). This excess surface area allows an RBC with a diameter of approximately 8 μm to twist, elongate, and deform sufficiently to squeeze through these 2 to 3-μm slits. The excess surface area, occasionally referred to as the *ratio of surface area to volume* (SA:V), is critical and is normally approximately 1.4. Any condition that reduces SA:V reduces the ability of RBCs to traverse these sinusoidal slits because plump spheres cannot deform sufficiently.

Factors that interfere with interaction of the cytosol and the membrane also impair the ability of the RBC to deform. Oxidant attack may produce Heinz bodies that come to lie adjacent to the membrane. They interfere with the smooth movement of the membrane over the cytosol, a process called *tank treading*. Such cells are selectively blocked from leaving the splenic cords and entering the sinuses. Inflammation or infection may enhance the ability of splenic macrophages to attack and ingest RBCs. Although not strictly a mechanism of hypersplenism, Kupffer cell erythrophagocytosis is a prominent finding in patients undergoing graft-versus-host hemolysis seen after liver transplantation.

The spleen is more complicated than other reticuloendothelial organs in that the afferent arterioles pass through lymphoid nodules (i.e., white pulp) and then terminate in the cords of Billroth (i.e., red pulp), into which blood cells are discharged. In the slow flow of the cords of Billroth, blood cells are selectively attacked by macrophages and are in direct contact with several classes of lymphocytes. The blood cells must then pass through the cordal walls before they can approach the sinus wall, which they must pass through to reenter the circulation. The spleen provides a double filter, and the blood cells must be remarkably deformable to pass through it. This slow passage permits highly selective action by macrophages, which have receptors that can detect several sorts of alterations in these blood cells. These receptors include the Fc receptor for the appropriate portion of the Ig molecule, receptors for complement components such as C3b, and perhaps receptors that detect alterations in the outer portion of the phospholipid bilayer or in the externally oriented glycopeptides. The macrophage then holds, retards, modifies (i.e., pitting function), or removes (i.e., culling function) the blood cells identified. Normally, the pitting function of the spleen allows it to remove Howell–Jolly bodies and normally occurring endocytic vacuoles (called *pocks* because of their appearance on phase interference or Nomarski microscopy). The normal culling function of the spleen is exemplified by its removal of senescent RBCs.

All the activities of the spleen presumably are markedly accentuated in a large spleen, and if the increased activity is sufficiently extensive, hypersplenism ensues. The size of the spleen, not the portal pressure, is important in determining the degree of RBC sequestration. Other factors that may play a role are the state of activation of the splenic macrophages and the size of the small slits between the splenic cords and sinuses. The macrophages and slits seem to be under a degree of control, as evidenced by variations in splenic removal of RBCs in patients with malaria.

The clinical picture of hypersplenic hemolysis is dominated by the specific cause of the splenomegaly. Although the causes of splenomegaly are legion, there are several general mechanisms (Table 48.1). Usually some degree of anemia is seen, with evidence of a compensatory increase in RBC production. Because stasis and trapping in the spleen are associated with macrophagic attack and remodeling of the RBC surface, the reduction in SA:V leads to spherocytosis. If the RBCs undergo a prolonged period of distortion when traversing the cordal–sinus barrier, tailed RBCs will be present as the RBC membranes undergo a plastic change (see Chapter 45). Because the enlarged spleen can trap and remove platelets and white blood cells, variable thrombocytopenia and leukopenia may occur. The bone marrow may show normal to increased cellularity with erythroid hyperplasia.

Management depends on the cause of splenic enlargement. The anemia or pancytopenia usually is not profound; however, splenectomy may be contemplated if the anemia is severe. Alternatives to splenectomy include splenic embolization and high-intensity focused ultrasound ablation. In most situations, recognition of the possibility of hypersplenism is most important in guiding the approach to the diagnosis of an unexplained anemia. Massive splenomegaly is frequently associated with the expansion of the plasma compartment, and measurement of hemoglobin, hematocrit, or RBC levels may give a falsely low value of the RBC mass present. In that circumstance, the true RBC mass can be determined by ^{51}Cr assay.

TABLE 48.1 **Causes of Splenomegaly**

Cause	Example
Neoplasia	Lymphoma, hairy cell leukemia
Infection	Bacterial endocarditis, malaria, schistosomiasis, tuberculosis
Portal bed obstruction	Alcoholic cirrhosis, splenic vein thrombosis
Collagen vascular disease	Systemic lupus erythematosus, malignant phase of rheumatoid arthritis
Chronic inflammatory disease	Rheumatoid arthritis
Chronic hereditary or acquired hemolytic anemia	Severe β-thalassemia, autoimmune hemolytic anemia
Lipidosis	Gaucher disease
Amyloidosis	AL and AA types
Tropical splenomegaly syndrome	Hyperreactive malarial splenomegaly syndrome

A good example of massive splenomegaly causing plasma volume expansion is tropical splenomegaly syndrome, also known as *hyperreactive malarial splenomegaly syndrome*. Diagnostic criteria include massive splenomegaly more than 10 cm below the costal margin with no other cause identified; immunity to malaria; elevated serum IgM levels; and clinical response to treatment with antimalarial drugs such as chloroquine, proguanil, or pyrimethamine and folic acid. The pathophysiology of the splenomegaly seems to be poorly controlled B-lymphocytic production of antibodies, and IgM stimulation may be a response to malarial antigens or an unidentified mitogen. Malarial parasites are almost never found. The apparent anemia is in large part caused by plasma volume expansion, although RBC survival is reported to be slightly attenuated. Antimalarial therapy for several months reduces spleen size, so splenectomy is unnecessary.

Infection

Infection can cause hemolytic anemia via several pathophysiologic mechanisms (Table 48.2).

TABLE 48.2 **Mechanisms by Which Infection Can Cause Hemolysis**

Mechanism	Example
Direct parasitization of red cells	Malaria, babesiosis
Immune mechanisms	Cold agglutinin hemolysis after infectious mononucleosis or mycoplasmal pneumonia (see Chapter 46)
Induction of hypersplenism	Malaria, schistosomiasis
Altered red cell surface topology	*Haemophilus influenzae* infection
Release of toxins and enzymes	Clostridial infection causing thrombotic thrombocytopenic purpura–hemolytic uremic syndrome, *Escherichia coli* 0197, HIV infection

Parasite Infections

The classic example of direct parasitization is infection by *Plasmodium falciparum* (see Fig. 48.1C), *Plasmodium vivax*, or *Plasmodium malariae*. Infection with malaria, primarily *P. falciparum*, is a major health problem in the developing world, causing an estimated 300 to 500 million infections and 1 to 3 million deaths annually.[10] The burden of disease rests most heavily on young children and pregnant women. *Falciparum* malaria can cause a life-threatening anemia, with severe anemia defined as hemoglobin less than 5 g/dL associated with parasitemia and a normocytic blood film.[10] Malaria is primarily a disease of the tropical developing world but is still seen in the United States and its territories, primarily as an import from outside the United States. Of the 1298 cases reported in the United States in 2008, 117 (9%) were classified as severe, two of which were fatal. In each of the malarias, sporozoites injected by the mosquito in its saliva make their way to liver cells. After 1 to 2 weeks, they become merozoites, which burst out of the liver cells and into the bloodstream. Then, in a remarkable process, the parasite, by means of its apical end and related organelles called *rhoptries*, attaches to a specific receptor on the RBC surface. For *P. vivax*, the Duffy blood group antigen appears to be involved.

P. falciparum binds to sialic acid residues on the RBC surface that are on glycophorin A. After specific attachment, a convulsive movement occurs during which the RBC engulfs the parasite by a process resembling receptor-mediated endocytosis. Upon invasion of the RBC, the malarial parasite starts digesting the hemoglobin, depositing the undigested heme in the form of hemozoin. Knobs appear on the RBC surface, and the RBC becomes a sphere. Many proteins of parasitic origin are inserted into the RBC membrane, and some appear to cluster underneath these knobs. A parasite protein called *mature parasite-infected erythrocyte surface antigen* binds to membrane protein 4.1, and another parasite protein called *ring-infected erythrocyte surface antigen* binds to β spectrin. Both spectrin and protein 4.1 are integral components of the membrane skeleton, and the consequence of the binding of malarial proteins is RBC membrane stabilization. Thus stabilized, the parasitized RBC can continue to survive while the parasite continues to digest its contents.[11]

The parasite recruits the RBCs metabolic machinery, degrades and ingests hemoglobin, and grows, eventually bursting out of the RBC, and the cycle begins again. The RBCs are lysed intravascularly as a consequence of direct parasitic destruction and extravascularly as a consequence of changes in the splenic microvasculature and in the activation state of the monocyte–macrophage system. Treatment consists of the use of appropriate antimalarials and the support of erythropoiesis, including the use of RBC transfusion or exchange (or both) when indicated.

The anemia of malarial infections also involves mechanisms distinct from the lysis of parasitized RBCs. Erythropoiesis is suppressed, leading to the suppression of erythroid precursors and inadequate reticulocytosis during acute infection.[12] This inadequate hematopoietic response may be exacerbated by underlying iron deficiency, hemoglobinopathies, or concomitant infection (e.g., HIV), all potential contributors to the severity of anemia. In addition, loss of uninfected erythrocytes plays a major role in the development of anemia, with an 8- to 10-fold greater loss of unparasitized RBCs compared with parasitized cells. Uninfected RBCs have reduced deformability, and the degree of reduced deformability correlates with the severity of infection. Poorly deformable RBCs likely are cleared by the spleen. A recent study in rats indicates that CD8 T-cell–dependent parasite clearance in the spleen is involved in the damage of uninfected RBCs and their subsequent destruction.[13] Evidence of in vivo removal of immature malarial forms prompts the question of whether "uninfected" cells that are lost represent previously infected cells that nevertheless remain abnormal. Insertion of a merozoite rhoptry protein, ring surface protein 2, on RBCs in which infection was aborted has been implicated in the clearance of unparasitized erythrocytes and erythroid progenitors. In addition, uninfected RBCs demonstrate increased binding of Igs that are probably nonspecific immune complexes. Acute malarial infection, particularly with *P. falciparum*, also leads to alteration in the splenic function that incites premature destruction of uninfected RBCs.[14]

The lifespan of transfused RBCs is likewise decreased. ^{51}Cr-labeled normal RBCs infused into patients infected with malaria demonstrate a shorter lifespan than in normal control participants; this effect may persist after clearance of the parasitemia. Alternatively, parasites can be removed from RBCs along with the RBC membrane by the process of pitting, producing parasite-free spherocytes. This mechanism potentially explains the observed disparity between anemia and parasitemia.

Other infections that have somewhat similar pathophysiologies include Carrión disease (i.e., bartonellosis), in which a bite from the sandfly injects *Bartonella bacilliformis*, which attaches to the RBC surface of up to 80% of erythrocytes and causes lysis, leading to the massive hemolysis that characterizes acute infection. It appears that the invasion of RBCs partly depends on the flagella of *Bartonella* spp. Incubation with antiflagellin antiserum reduces invasion of RBCs. The bacteria also secrete deformin, a factor that leads to deep pitting on the surface of RBCs, presumably providing a portal of entry into the erythrocyte. There also may be a role for splenic clearance of infected cells, and prior splenectomy appeared to protect a patient from hemolysis during acute infection.

Babesia organisms also directly invade RBCs by mechanisms somewhat resembling those seen is in malaria,[15] producing fever and hemolytic anemia. The parasite is transmitted by ticks and transfusions of infected blood products[16] and can be transmitted vertically. Most tick-borne cases occur on the West Coast, particularly in Washington and California, and in the northern portion of the Midwest; cases occurring on the East Coast are concentrated in Massachusetts and Nantucket Island. However, transfusion-associated cases have been reported throughout the United States.[16] In one report of transfusion-associated babesiosis, the median interval from transfusion to onset of clinical manifestations was 37 days. The organisms can be seen invading RBCs on smear examination, somewhat like *P. falciparum* malaria, but these organisms produce no pigment. The highest risk of death from babesiosis occurs in individuals who are older than 50 years or are immunocompromised because of acquired immunodeficiency syndrome (AIDS), drugs, transplantation, or asplenism. Sporadic reports indicate that acquired chronic toxoplasmosis is occasionally associated with hemolytic anemia.

Alteration of the Red Blood Cell Surface by Bacterial Products

Infection can produce hemolysis by altering the RBC surface. An example is the hemolysis caused by *Haemophilus influenzae* type b. Severely affected patients, particularly those with meningitis, have developed hemolytic anemias requiring RBC transfusions. The capsular polysaccharide of the bacterium, composed of polyribosyl ribitol phosphate (PRP), is released during infection and binds to the RBC surface. Infected patients develop antibodies to PRP. When the balance between PRP-coated RBCs and anti-PRP antibodies is correct, an immune-type hemolysis occurs and requires a complement. RBC destruction is thought to be both intravascular and extravascular.

Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells

The most dramatic example of hemolysis caused by bacterial action is clostridial infection, during which the organism releases enzymes that acutely degrade the phospholipids of the membrane bilayer and the structural membrane proteins. The resulting spherocytes are extremely sensitive to osmotic lysis. The setting can be any infection, but our experience is limited to acute cholecystitis, surgery of the biliary tree, and infections surrounding an obstetric event, including criminal or self-induced abortion, or other infection of the gravid uterus. Patients may also have an underlying gastrointestinal, genitourinary, neuroendocrine, or hematologic malignancy.[17] The signs of infections may be obvious, but fever may be unimpressive. Signs of collapse appear acutely, and the clue is profound intravascular hemolysis, with a spherocytic anemia developing with shocking suddenness. The blood smear characteristically has numerous spherocytes with little evidence of microangiopathy, may be tinged red because of marked hemoglobinemia, and may have ghost cells. A clue to the severity of the process may be the inability of the laboratory to perform chemical determinations or to type and cross-match the blood because the sample is hemolyzed. With even the slightest suspicion of hemolysis caused by bacterial action, the physician immediately starts full doses of penicillin and clindamycin; evaluates the patient for DIC (see Chapter 137); and prepares to support the patient for shock, DIC, acute renal failure, and hemolytic anemia. Whether hysterectomy is lifesaving in the case of septic abortion is unclear.

Hemolysis Caused by Less Well Understood Infections

HIV infection can cause Coombs-positive autoimmune hemolytic anemia, a TTP-like syndrome, and microangiopathic hemolysis. CMV infection has been reported to cause severe Coombs-negative hemolytic anemia in immunocompetent adults.[18] Case reports of autoimmune hemolytic anemia and HUS associated with CMV infection have emerged. The hemolytic anemia in visceral leishmaniasis may be caused in part by the generation of oxidative metabolic products. Severe microangiopathic hemolytic anemia has been described in cases of cutaneous anthrax.

Hemolysis Associated With Liver Disease

Hemolysis in liver disease by itself usually is not of overwhelming clinical importance, but it may contribute to the severity of anemia when coupled with defects in RBC production and the type of gastrointestinal blood loss that occurs in several forms of liver disease. Hemolysis in patients with liver disease has several causes. The spleen may be enlarged as a consequence of portal hypertension and produce a hypersplenic picture, a phenomenon seen commonly in hepatic cirrhosis.

A classic red cell manifestation of liver disease is the appearance of target cells. The literature on RBC shape change in liver disease is considerable. The target cell in cirrhosis has an increased SA:V that appears to be a consequence of increased cholesterol and phospholipid content of the membrane bilayer. The cholesterol increase is usually proportionately greater, resulting in an increased cholesterol-to-phospholipid ratio. This increase in lipid probably accounts for the increased RBC surface area, such that more membrane than usual is present in relation to cellular contents. These RBCs probably circulate as bell-shaped RBCs called *codocytes*. However, on dried blood films, they assume the appearance of target cells. Target cells do not have a shortened survival. Their volume (MCV) is in the normocytic range, in contrast to the microcytic target cells seen in thalassemia (Chapter 40) and in advanced iron deficiency anemia (Chapter 36). The RBCs of patients with liver disease frequently are echinocytes when wet preparations are examined, but these echinocytes are not easily apparent on dried blood smears. The echinocytes seem to be produced by a material in the patient's plasma that causes normal RBCs to become echinocytic; this material is an abnormal echinocytogenic high-density lipoprotein. Echinocytes do not necessarily have a shortened survival. Some forms of echinocytic RBCs are normally deformable when studied in the ektacytometer or rheoscope.

A brisk, clinically important hemolysis can occur in some patients with severe liver disease. The peripheral smear in these individuals usually shows acanthocytes (i.e., distorted RBCs). Extreme forms are called *spur cells*, which are probably acanthocytes additionally remodeled by an enlarged spleen and are considerably enriched in cholesterol. They are rapidly removed in the spleen, which is usually enlarged.

Increased RBC membrane proteolytic activity may be a partial explanation for the differences between acanthocytosis and spur cells, and additional pathophysiologic mechanisms may be involved. Although the adult RBC cannot synthesize phospholipids de novo, it can identify and remove peroxidized fatty acid chains that interfere with normal membrane lipid fluidity. When the fatty acid is removed, a lytic lysoderivative remains; therefore, the missing fatty acid chain must be replaced. A store of acyl groups in the form of acylcarnitine exists in RBC membranes. When needed, the fatty acid (i.e., acyl group) is transferred to acyl-coenzyme A and then inserted into the potentially lytic lysophospholipid by the enzyme lysophosphocholine acyltransferase. Lysophosphocholine acyltransferase is inhibited in spur RBCs, and the same inhibition can be produced by heavily loading RBCs with cholesterol in vitro.

In spur cell anemia, the RBCs have an abnormal membrane SA:V ratio, their membrane fluidity is impaired, and they are unable to remove and repair peroxidatively damaged fatty acids. Occasionally, spur cell hemolytic anemia is severe enough to necessitate the consideration of splenectomy. Operative morbidity in such cases is considerable because the underlying liver disease usually produces problems with thrombocytopenia and leukopenia, as well as with procoagulants and intolerance to anesthesia. Spur cell anemia is typically associated with alcoholic cirrhosis, but it can also be seen in patients with nonalcoholic cirrhosis. The anemia tends to be severe and portends a poor prognosis. Transfusions are of limited efficacy because the membrane abnormalities are acquired by transfused RBCs.[19]

Acute alcoholism can be associated with hypophosphatemia, defined as levels less than 0.2 mg/dL. Such hypophosphatemia presumably interferes with RBC intermediary metabolism (see Chapters 33 and 44), and RBC adenosine triphosphate (ATP) levels fall. Very low ATP levels are associated with RBC rigidity, which leads to fragmentation, loss of surface area, and spheroidicity. The RBCs then are further trapped in the spleen. This hypophosphatemia syndrome can also cause neuromuscular disorders, including weakness, paresthesias, tremors, and seizures. It should be treated aggressively with orally and intravenously administered phosphate supplements. Hypophosphatemia also occurs in patients with cirrhosis, patients receiving total parenteral nutrition whose phosphate intake is not carefully monitored, and patients taking large amounts of phosphate-binding antacids.

Stomatocytosis can occur in severe liver disease and is thought to be a sign of acute alcoholic intoxication. The change in RBC shape can also be seen in acute pancreatitis. The stomatocyte is a cell well on its way to becoming a spherocyte. The reduction in SA:V leads to trapping in the microvasculature of the spleen and other organs of the monocyte–macrophage system, producing various degrees of hemolysis.

Hemolysis in Renal Disease

The anemia in renal disease is multifactorial. A major component is impaired RBC production, which can be well controlled with erythropoietin. Renal disease also impairs platelet function, which may lead to occult blood loss. However, hemolysis also can occur and is multifactorial. Disease of the small renal arterioles can produce fragmentation hemolysis of the sort seen in TTP–HUS, preeclampsia, and malignant hypertension (see the box on Causes of Red Blood Cell Fragmentation Hemolysis). Otherwise, whether uremia produces significant shortening of RBC survival is not clear. Patients with chronic renal failure who are undergoing hemodialysis may be particularly susceptible to oxidative damage to their RBCs. RBC glutathione is reduced in some patients, and the activity of the enzymes G6PD and glutathione peroxidase is relatively low. The ability of these RBCs to deal with the generation of peroxides probably is impaired.

Venoms, Bites, Stings, and Toxins

The best-known example of toxin-caused hemolysis is discussed in the earlier section, Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells.

Insect, Spider, and Snake Bites

Hemolysis occurs after bee and wasp stings, snake bites, and spider bites. Isolated cases of acute intravascular hemolysis after bee and wasp stings have been reported. Two kinds of dangerous spiders live in the United States: the southern black widow and the brown recluse spider. Both sexes of the black widow produce the venom, but only the female has fangs capable of penetrating human skin. Black widow spider bites produce generalized muscle pain and muscular rigidity. Hemolysis is not common. Brown recluse spider bites cause a considerable local reaction, called the *volcano lesion*. DIC and hemolysis may occur after a lag of 24 to 48 hours. Envenomation results in cleavage of RBC glycophorins, presumably making the RBCs more susceptible.[20] Corticosteroids may be beneficial. The hemolysis appears to be self-limiting, but RBC transfusion support may be needed.

In some parts of the world, cobra bites can cause intravascular hemolysis because the venom contains phospholipases. In the United States, the two classes of venomous snakes are pit vipers (e.g., rattlesnakes, cottonmouths, moccasins, and copperheads) and coral snakes. Pit viper venom affects hemostasis and may produce DIC with bleeding but rarely hemolysis. Coral snake venom produces severe neurologic impairment. Therapy consists of support and use of the appropriate antivenin and prophylactic antimicrobials and tetanus injections.

Drugs and Chemicals Exclusive of Those Producing Oxidative Hemolysis

Potassium Chlorate

Potassium chlorate ingestion is listed as a cause of hemolysis, but this compound is no longer available in hospital pharmacies and has no currently recognized medical use. Arsine gas is generated in industrial plants that engage in lead plating, galvanizing, etching, and soldering. Inhalation of a toxic amount produces a severe intravascular hemolysis of unknown pathogenesis and may require urgent RBC and plasma exchange.

Copper

The idea that copper can produce human hemolytic disease is best supported by observations of episodes of severe hemolysis and acute liver failure in patients with Wilson disease. The patient usually is a child, adolescent, or young adult for whom the diagnosis of Wilson disease has not yet been made. The initial clinical presentation is usually dominated by Coombs-negative hemolytic anemia accompanied by weakness and dark urine. Associated findings include coagulopathy, a rapid progression to renal failure, relatively modest rises in serum aminotransferases, and a low alkaline phosphatase level. In addition to the presence of a brisk reticulocytosis, the typical findings of intravascular hemolysis may be present, including elevated lactate dehydrogenase, low haptoglobin, and markedly elevated bilirubin levels. Review of the peripheral smear may not reveal any specific morphologic findings, although both stomatocytosis and blister cells consistent with oxidant injury have been described. In one reported patient with concomitant transfusion-dependent hemoglobin E/β thalassemia, the acute hemolysis led to a severe unexpected drop in the posttransfusion hemoglobin level. Because of the hereditary deficiency in the copper-binding protein ceruloplasmin, urine and serum nonceruloplasmin–bound copper levels in patients with hemolysis are very high.

Free copper can interfere with glucose metabolism by hexokinase inhibition and alternatively can generate oxidative hemolysis, perhaps by acting as a Fenton reagent. It is important to establish the diagnosis promptly. When this condition is suspected, the practitioner should look for Kayser–Fleischer rings on physical examination and measure serum and urine copper and ceruloplasmin levels. Treatment with penicillamine or trientine plus zinc reduces the serum copper level and stops the hemolysis.[21] In the case of acute liver failure, the treatment is urgent liver transplantation. Plasmapheresis and hemofiltration may be beneficial in reducing the copper level and can serve as a bridge to transplant. In some cases, plasmapheresis in combination with chelation therapy or the use of a fractionated plasma separation and adsorption dialysis system may avert the need for transplant in impending acute liver failure. Other forms of copper poisoning may cause hemolysis in patients who do not have underlying Wilson disease. The amount of copper ingested would have to exceed the copper-binding capacity of normal ceruloplasmin levels.

Lead

There are at least two general forms of lead intoxication. One type is chronic, slow cumulative poisoning (i.e., saturnism). An example is occupational exposure. Symptoms are predominantly neurologic and nephrologic, with variable degrees of anemia, which may be caused by a production defect combined with hemolysis. Relatively acute poisoning occurs when lead inadvertently finds its way into a food source or is consumed as part of an exotic medication. Subacute lead poisoning leads to central nervous system symptoms, hepatitis, nephrotoxicity, hypertension, and abdominal colic along with seizures and severe hemolytic anemia. Physical examination may reveal a lead line on the gums. Peripheral smear shows extensive coarse basophilic stippling and reticulocytosis; however, RBC morphology is not otherwise characteristic. Some researchers state that intravascular destruction occurs, but no proof has been provided. Bilirubin levels are not significantly elevated.

The diagnosis of lead-related hemolysis can be made from the history and findings on physical examination, including a lead line on the gingiva and coarse basophilic stippling on RBCs, reflecting the pathologic aggregation of ribosomes. The diagnosis is confirmed by measuring blood and urine lead levels. The level of acuity determines the therapy.

The cause of the anemia is complex. Lead interferes with several steps in heme synthesis, particularly those involving heme synthetase and δ-aminolevulinic acid dehydratase (see Chapter 38). The inhibition of heme synthetase probably accounts for the elevation in free erythrocyte protoporphyrin, providing a useful corroborative diagnostic test for lead toxicity. Inhibition of heme synthesis also probably accounts for the elevated urinary levels of δ-aminolevulinic acid and coproporphyrin. Lead poisoning mimics the basophilic stippling and accumulation of pyrimidines seen in hereditary deficiency of the enzyme pyrimidine 5′-nucleotidase, probably because lead attacks the enzyme (see Chapter 44).

Ribavirin

A current treatment for chronic hepatitis C virus (HCV) infection may consist of combination therapy with pegylated interferon (IFN) and ribavirin, a nucleoside analog. Ribavirin's activity against HCV includes inhibition of inosine monophosphate dehydrogenase, a key step in de novo guanine synthesis. Treatment with ribavirin may produce dose-dependent hemolytic anemia, which is typically reversible 1 to 2 months after discontinuing treatment.[22] The hemoglobin drops by an average of 2 to 3 g/dL and may fall below 11 g/dL in one-third or more of patients. The anemia may necessitate a dose reduction of ribavirin or may be treated with recombinant erythropoietin at 40,000 units weekly. A decrease in the total cumulative dose of ribavirin may be associated with decreased sustained virologic response, which would suggest that dose reduction secondary to anemia would have an adverse impact on treatment efficacy. However, in one retrospective study, a drop in hemoglobin of greater than 3 g/dL was instead associated with improved sustained virologic response rate compared with those with a drop in hemoglobin 3 g/dL or less,[23] suggesting conversely that the degree of hemolytic anemia may serve as a biomarker of efficacy. Ribavirin is transported into the erythrocytes and accumulates as ribavirin monophosphates, diphosphates, and triphosphates.[22] The steady-state concentration of ribavirin in erythrocytes is approximately 100-fold higher than that of plasma, and higher erythrocyte ribavirin levels correlate with worsened anemia during therapy. The accumulation of phosphates leads to a decrease in ATP levels compared with control erythrocytes. Because ATP is required to generate the glucose-6-phosphate needed for glycolysis and the hexose monophosphate shunt, reduced levels of ATP may lead to oxidative damage, as evidenced by increased aggregates of band 3, which bind anti-band 3 IgG and complement. The ribavirin prodrug viramidine induces less anemia than ribavirin, although efficacy was decreased when used at fixed doses compared with a ribavirin-containing regimen. Fellay et al.[24] have detected two polymorphisms in the inosine triphosphatase (*ITPA*) gene, which encodes a protein that hydrolyzes inosine triphosphate, that were protective against severe anemia in patients treated with HCV. These two polymorphisms were associated with reduced *ITPA* activity and accumulation of inosine triphosphate in RBCs. The mechanism of this protective effect is not yet fully understood. The anemia in patients treated with ribavirin may be exacerbated by concomitant treatment with pegylated IFN, which suppresses hematopoiesis, and may also be associated with autoimmune hemolytic anemia. Anemia may also be exacerbated when ribavirin and IFN are used in combination with the protease inhibitor, a regimen that is efficacious in the treatment of genotype 1 disease.

DRUG-INDUCED OXIDATIVE HEMOLYSIS

General Concepts

The potential for normal RBCs to undergo auto-oxidative destruction is great because the cell is loaded with 20-mM hemoglobin, most of which is bonded to oxygen at the iron(Fe^{++}) atom in heme. The bond that allows the reversible association and dissociation of oxygen from the heme moiety of hemoglobin involves the partial transfer of an electron from iron(Fe^{++}) to oxygen. Consequently, oxygen then has an extra electron, making it a superoxide radical. Ordinarily, when oxygen leaves hemoglobin, it returns the electron. If it does not, a highly reactive superoxide ion is released, leaving behind it an iron(Fe^{+++}) moiety called *methemoglobin*.

$$HbFe^{2+}O_2 \rightarrow HbFe^{3+} + O_2^{-1}$$

Methemoglobin cannot reversibly bind oxygen. Methemoglobin in itself is not harmful to RBCs, but if the oxidative assault persists, methemoglobin is converted to hemichromes, which are variably denatured hemoglobin intermediates in which the distal histidine unit binds to the oxidized heme. This step is associated with conversion from a high to a low spin state, as measured by electron spin resonance. Continued oxidation leads to the irreversibility of hemichrome oxidation, precipitation, and eventually the formation of Heinz bodies. Hemichromes and Heinz bodies can destroy membrane function directly or by causing the oxidation of membrane proteins and lipids.[25] Approximately 3% of hemoglobin is converted to methemoglobin each day, but the finding that only 1% of hemoglobin normally is in the form of methemoglobin indicates that mechanisms preventing oxidation in RBCs are in effect. These mechanisms are limited because RBCs lack the ability to either efficiently generate ATP or synthesize enzymes. The primary means for preventing or addressing oxidant injury are the generation of the reduced form of nicotinamide adenine dinucleotide (NADH) via the Embden–Meyerhof glycolytic pathway and the generation of nicotinamide adenine dinucleotide phosphate (NADPH) via the hexose monophosphate shunt. NADH is used to reduce methemoglobin by cytochrome b5 reductase, and NADPH is used to reduce glutathione and for catalase activity. Defects in this defense system against oxidation lead to an enhanced tendency to oxidative hemolysis. Examples are G6PD deficiency states.[26] G6PD catalyzes the initial rate-limiting step in the hexose monophosphate shunt. Deficiencies lead to a reduced ability to generate NADPH in response to oxidant stress. Any agent or event that interferes with the smooth offloading of oxygen enhances the generation of O_2^{-1} and methemoglobin, as indicated in the equation. If the reducing power of the RBC is inadequate, hemichromes and Heinz bodies are generated. Many agents appear to cause oxidative hemolysis by interfering with the smooth functioning of the heme cleft.

REDUCTION OF DANGEROUS METHEMOGLOBIN LEVELS

Levels of methemoglobin in excess of 20%–30% can be dangerous, but they can be easily treated with methylene blue (1–2 mg/kg) infused intravenously over 5 min as 0.1–0.2 mL/kg of a 1% solution. In the presence of a functioning, intact reduced form of nicotinamide adenine dinucleotide phosphate (NADPH)–methemoglobin reductase system, methylene blue is reduced to leukomethylene blue, which reduces methemoglobin to hemoglobin.

Pathophysiology

After the oxidative attack has been initiated, the sequence proceeds along a recognizable track. The oxidative attack is directed at hemoglobin and the RBC membrane. However, these structures are not clearly separable because the precipitated hemichrome and Heinz bodies come to lie against the cytosolic face of the membrane. Methemoglobin may be detectably elevated, with levels as high as 50% to 60% of total hemoglobin. The hemichromes, by themselves or with their iron portions acting as a Fenton reagent, mediate the generation of hydroxyl free radicals, which add their effect to that of superoxide and hydrogen peroxide. Lipid peroxidation may take place, leading to membrane blebbing and cell lysis, as well as the loss of asymmetry of the phospholipid membrane bilayer. Movement of phosphatidylserine and phosphatidylethanolamine to the outer bilayer of the membrane results in increased recognition by macrophages in the reticuloendothelial system. Membrane proteins may be crosslinked, with binding of denatured, oxidized hemoglobin to the membrane cytoskeleton, which may increase splenic macrophage recognition. In addition, the RBCs are rigid and susceptible to trapping in sinusoidal structures, whether or not they have Heinz bodies lying against the membrane. In vitro evidence suggests that oxidized RBCs are increasingly susceptible to phagocytosis by macrophages. These features may account for extravascular destruction. The oxidative lesions can be severe enough to cause intravascular destruction as well, producing hemoglobinemia and hemoglobinuria.

The smear may show bite cells, which look as if a macrophage had taken a bite, removing a Heinz body-containing segment of the membrane. RBC rigidity may result in irregularly shaped cells because these undeformable cells are unable to undergo elastic recoil after fighting their way through the sinus wall. Recurrent loss of membrane material may produce spherocytes. Severe hemolysis may produce the kind of circulating ghost or hemighost called a *blister cell* or *bite cell*. These RBCs have an empty veil of membrane on one side and puddled hemoglobin on the other. A Heinz body preparation may be positive. However, the absence of bite cells does not rule out the diagnosis.

The clinical picture is determined by the specific agent used. Screening for G6PD deficiency or a related disorder using an enzyme assay or the ascorbate cyanide test may be useful (Chapter 44). Although any defect in the antioxidant defense mechanisms, such as G6PD deficiency, considerably increases the susceptibility to hemolysis, many agents can produce oxidant hemolysis even in persons with normal defense mechanisms (see the box on Agents That Cause Oxidative Hemolysis).

Paraquat ingestion has occurred inadvertently and in suicide attempts. Profound cyanosis with methemoglobinemia can occur within hours, with levels of 120% or higher. The condition may be succeeded by hemolysis, with Heinz bodies seen in appropriate preparations of RBCs.

AGENTS THAT CAUSE OXIDATIVE HEMOLYSIS

- Therapeutic agents
  - Nitrofurantoin (Furadantin)
  - Sulfasalazine (Azulfidine)
  - *p*-Aminosalicylic acid
  - Phenazopyridine (Pyridium)
  - Clotrimoxazole
  - Quinolones
  - Phenacetin
  - Rasburicase
  - Dapsone and other sulfones
  - Primaquine
- Recreational drugs
  - Isobutyl nitrate
  - Amyl nitrite
- Miscellaneous agents
  - Naphthalene mothballs
  - Methylene blue
  - Paraquat
  - Hydrogen peroxide

Toxic ingestion or inhalation of nitrites may occur in suicide attempts from industrial exposures; via diets high in pickled or smoked foods; through intentional recreational use; or in infants from formulas prepared using well water high in nitrates, which are reduced to nitrites in the infant gut.[27] Nitrites bind to hemoglobin, producing methemoglobinemia, which may be so profound as to produce coma. If methylene blue infusion does not quickly turn the chocolate color of blood back to normal, the physician must consider the possibility that the patient is G6PD deficient and therefore unable to generate adequate amounts of NADPH (discussed earlier in the section Drug-Induced Oxidative Hemolysis: General Concepts). In that case, exchange transfusion may be lifesaving. Benzocaine topical anesthesia in the form of a spray or cream can cause severe methemoglobinemia, with cyanosis and dyspnea requiring methylene blue treatment.

In a case of almost fatal oxidative hemolysis, hydrogen peroxide was injected directly into the Hickman catheter of a patient with AIDS because some persons infected with HIV had circulated a pamphlet suggesting that hydrogen peroxide could be used therapeutically to control HIV infection. We now are seeing AIDS patients with dapsone-induced methemoglobinemia and hemolytic anemia (see Chapter 44). Methemoglobinemia, if severe, is treated as described in the preceding paragraph and in Chapter 44.

Pyridium (phenazopyridine) can cause oxidative hemolysis even in the absence of renal disease. This agent is commonly used for the treatment of bladder irritation. The *Physician's Desk Reference* recommends maximum therapy of 2 days. However, patients not uncommonly are given a prescription for 1 to 4 weeks of therapy.

It has been recognized for more than 130 years that therapy with dapsone causes oxidative hemolysis. In the past, dapsone was used primarily to treat leprosy and dermatitis herpetiformis and was not often encountered as a cause of oxidative hemolysis. Dapsone has come into more widespread use in some communities as a very effective prophylactic agent against *Pneumocystis carinii* pneumonia in patients with AIDS. The reduced levels of glutathione reported in patients with AIDS may enhance dapsone toxicity. Dapsone is also used in the treatment of malaria where it regularly causes hemolytic anemia in G6PD-deficient patients.[28] Some clinics screen potential recipients for G6PD deficiency (see Chapter 44) and, if results are negative, proceed with dapsone therapy. However, dapsone can cause oxidative attack on normal RBCs, leading sequentially to methemoglobinemia, Heinz bodies, and hemolysis, all occurring at generally accepted standard doses. Dapsone is metabolized to a hydroxylamine derivative that is directly toxic to RBCs.

MISCELLANEOUS, POORLY CHARACTERIZED CAUSES OF EXTRINSIC HEMOLYTIC ANEMIAS

Interferon-α as a Cause of Hemolytic Anemia

Both microangiopathic and autoimmune hemolysis have been reported with IFN-α use. Zuber et al.[29] reported eight patients with chronic myeloid leukemia who developed thrombotic microangiopathy confirmed by renal biopsy. Seven of these patients had identifiable hemolysis, and three had thrombocytopenia. They also reviewed 13 other cases of microangiopathy associated with IFN-α reported in the literature and observed that most cases occurred in the setting of prolonged therapy in chronic myeloid leukemia. Two cases of chronic hepatitis with microangiopathy were notable for having received unusually high doses of IFN for this indication. Cases of autoimmune hemolysis have been reported with IFN-α therapy in the setting of chronic myeloid leukemia or chronic hepatitis C.

Hemolysis With Intravenous Immunoglobulin G

Strictly speaking, hemolysis with intravenous IgG is a form of immune hemolysis. However, preparations of IgG contain anti-A and anti-B antibodies and rarely cause an alloimmune hemolytic anemia, as described in two young women undergoing treatment for idiopathic thrombocytopenic purpura. If this situation occurs and more intravenous IgG is needed, performing a minor cross-match and choosing a preparation of intravenous IgG that gives no reaction is recommended. In addition to isoantibody production, anemia has been reported with intravenous IgG because of immune complex-mediated complement activation.

For hemolytic anemia with large granular lymphocyte leukemia, see the box on Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia.

HEMOLYTIC ANEMIA IN CHRONIC LARGE GRANULAR LYMPHOCYTIC LEUKEMIA

Although large granular lymphocytic leukemia usually manifests as neutropenia and a rheumatoid-like picture, several patients with a severe Coombs-negative hemolytic anemia in the absence of splenomegaly have been described. Large granular lymphocytic leukemia has occurred in a splenectomized patient. The mechanism is unknown, but one report identified direct cytotoxicity against red blood cells (RBCs) by the large granular lymphocytic cell lines.

There have been no formal studies on therapy for large granular lymphocytic leukemia-related hemolysis, although immunosuppressive therapy with prednisone or methotrexate has been reported as being partially or wholly successful.

ACKNOWLEDGMENT

Dr Stanley Schrier, the author of the first version of this chapter, died in 2019. His contribution to this present chapter is gratefully acknowledged.

CHAPTER 49

NEUTROPHILIC LEUKOCYTOSIS, NEUTROPENIA, MONOCYTOSIS, AND MONOCYTOPENIA

Lawrence Rice, Arthur W. Zieske, and Moonjung Jung

Abnormalities of leukocyte number are commonly encountered in medical practice. The clinical significance of leukocytosis or leukopenia varies from none at all to being an early clue to a life-threatening process, whether that is a primary hematologic or secondary reactive process. Potential causes of leukocytosis or leukopenia are myriad. This chapter considers disorders faced by adult practitioners in hospital and outpatient clinics where the predominant hematologic abnormality is neutrophilic leukocytosis, neutropenia, monocytosis, or monocytopenia; other chapters consider lymphocytosis, lymphopenia, eosinophilia, pancytopenia, and hematologic neoplasms.

The normal range for leukocyte count in most laboratories is from about 4500/mm^3 to 11,000/mm^3. Neutrophils (and band forms) comprise the majority of circulating leukocytes (1800 mm^3 to 7700/mm^3). Monocytes are about 4% of cells (mean absolute count: 300/mm^3). The physician should always think in terms of absolute counts of leukocyte subpopulations (total leukocyte count multiplied by the differential percentage). Thus, in a patient presenting with a normal white blood cell (WBC) count of 5000/mm^3 and an elevated lymphocyte percentage of 65%, the differential diagnosis to be considered is that of neutropenia, not lymphocytosis, because the absolute neutrophil count (ANC) is decreased but absolute lymphocytes are normal (only relatively increased).

When approaching a patient with abnormal leukocyte number, several factors impact heavily on the differential diagnosis and the vigor with which diagnosis and therapy should be pursued. Diagnostic considerations are vastly different when the abnormality first manifests **in the hospital versus in the outpatient clinic**. Also crucial is the **degree of the abnormality**, providing guidance to its likely cause and consequence. For example, agranulocytosis (Fig. 49.1) is a life-threatening disorder in which neutrophils are at or near zero, has a limited spectrum of underlying causes (drug reactions being paramount), and demands immediate interventions. **Duration** has major implications; determining the onset of changes and whether they are stable or progressive informs as to etiology and significance. Whether the abnormality is **symptomatic**—for example, whether a neutropenic or monocytopenic patient has or has had infectious complications—bears on likely etiologies and need for therapy. If there are known or suspected **comorbid conditions**, such as autoimmune or inflammatory disorders, this can crystallize the approach; occasionally, the leukocyte abnormality may be the first sign of a previously unrecognized disorder or may provide important confirmation (e.g., neutropenia in a patient with systemic lupus erythematosus [SLE]). If the leukocyte abnormality is accompanied by **additional hematologic abnormalities** (unexplained abnormalities of red blood cells [RBCs], platelets, or cell morphology), this would point away from disorders considered in this chapter and often toward a primary hematologic disease. Beyond history and physical examination, the peripheral blood smear is key to establish the direction of further evaluation.

NEUTROPHILIC LEUKOCYTOSIS (NEUTROPHILIA)

A high WBC count, particularly a high neutrophil count, is common with any infectious or inflammatory disorder. In the emergency department, leukocytosis is often equated with significant bacterial infection or is at least a sign of illness severe enough to warrant hospital admission rather than outpatient management. Leukocytosis can also be a prominent presenting feature of leukemias and myeloproliferative neoplasms (MPNs). The presence of increased neutrophils assures that acute leukemia is not present. When leukocytosis is extreme, it indicates chronic myeloid leukemia (CML), other MPNs, or a leukemoid reaction.

Leukemoid reaction has been defined as a reactive (nonclonal) neutrophilic leukocytosis with WBC count above 50,000/mm^3. This must be differentiated from a neoplastic proliferation.

Leukoerythroblastosis (Fig. 49.2) refers to the presence in the peripheral blood of immature myeloid cells (generally myelocytes) and nucleated RBCs, often with giant platelets as well. This is always abnormal. Patients with leukoerythroblastosis do not necessarily have leukocytosis, but they usually do. Most patients (two-thirds) with leukoerythroblastosis have an underlying myelophthisic process, such as primary or secondary myelofibrosis, metastatic tumor, necrosis, or granulomas in the bone marrow (BM). Therefore, BM examination is indicated when leukoerythroblastosis is unexplained. Teardrop poikilocytes and elliptocytes on blood smear would strengthen concerns for myelophthisis. In 20% of patients with leukoerythroblastosis, the cause is hemolytic anemia, and miscellaneous other causes consist mainly of those with shock (septic, hemorrhagic, cardiogenic, anaphylactic) when hypoperfusion of areas of BM disrupt the microenvironment and permit disorderly egress of precursor cells.

Left-shifted neutrophils refer to relative immaturity of circulating cells, often manifest as an increased percentage of band neutrophils. Marked left-shift includes less mature precursor forms, myelocytes and metamyelocytes. Left-shift is nonspecific and may occur with infection or any cause of marked neutrophilia.

Detailed directed history and physical examination are indispensable to the evaluation of neutrophilia (Table 49.1). Fever and chills suggest infection (or inflammation), mandating a search for more specific symptoms that could pinpoint the focus. Examples include a sore throat, pharyngeal erythema, and exudate in pharyngitis; productive cough and abnormal lung auscultation in pneumonia; and dysuria and flank tenderness in urinary tract infection. Medication history mainly explores glucocorticoid use. With mild chronic neutrophilia, smoking habits and obesity become considerations. Recent vigorous exercise, emotional stress, burns, shock, or trauma can increase circulating neutrophils because of catecholamine-induced demargination. A positive family history may suggest hereditary neutrophilia. Often neglected are attempts to delineate the time course of the leukocyte abnormality by seeking prior medical contacts and blood count results at the time. On physical examination, care should be directed to lymph node palpation because this can be an important clue for infection or malignancy. Palpable splenomegaly may not only direct the evaluation toward hematologic disorders but can be a cardinal sign of a variety of infectious and inflammatory disorders.

Blood smear should always be a part of initial evaluation when there are abnormalities of blood counts. BM aspirate or biopsy morphology may be helpful when pathophysiology and diagnosis are unclear. When appropriate, essential information can be gained by sending BM for microbiologic cultures, cytogenetic or molecular, or other ancillary studies.

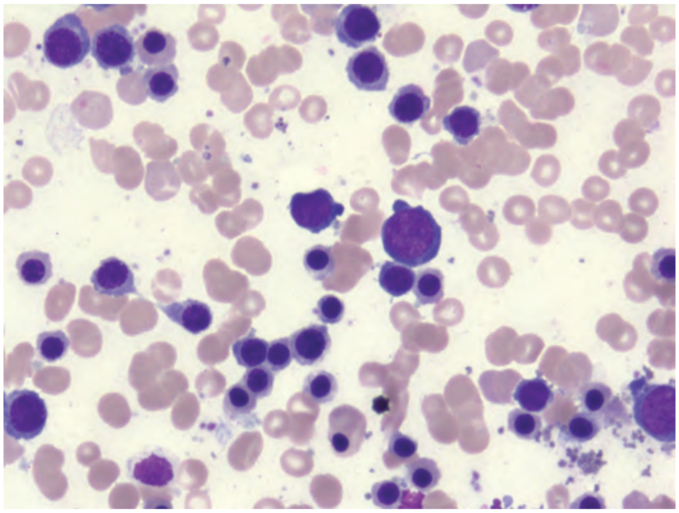

Figure 49.1 AGRANULOCYTOSIS (PURE WHITE CELL APLASIA) (bone marrow aspirate). Virtual absence of myeloid precursors. Most often due to drug reactions, but can be due to immunologic disorders.

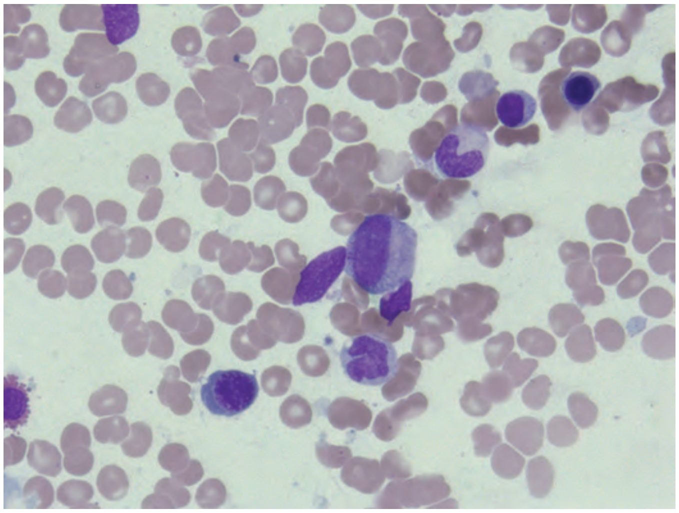

Figure 49.2 LEUKOERYTHROBLASTIC SMEAR (peripheral blood). The presence of immature myeloid cells (myelocytes) and nucleated red blood cells, often with giant platelets. Most often due to myelophthisis (marrow invasion by tumor, fibrosis, granulomas), but also due to hemolytic anemia or shock.

TABLE 49.1 **Causes of Neutrophilia**

1. Hematologic malignancy (CML, CNL, CMML)
2. Infection
3. Inflammation, physiologic stress, hemorrhage, hemolysis
4. Hereditary or congenital neutrophilias
5. Smoking
6. Drugs: colony-stimulating factors, glucocorticoids, epinephrine, lithium
7. Nonhematologic malignancy
8. Asplenia
9. Obesity
10. Recovery from neutropenia
11. Chronic binge drinking

CML, Chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *CNL*, Chronic neutrophilic leukemia.

Leukemoid Reaction Versus Chronic Leukemia

A relatively common reason for hematologic consultation is for very high WBC count. CML is reviewed elsewhere in this text book, as are chronic myelomonocytic leukemia (CMML) and the very rare chronic neutrophilic leukemia. Marked neutrophilic leukocytosis or overt leukemoid reaction (WBC count >50,000/mm^3) can represent an overly exuberant reaction to any stimulus associated with neutrophilia.[1] Infection is the most common non-hematologic cause of leukemoid reaction. In patients with leukemoid reaction, a disproportionate number have infection with *Clostridioides* (formerly *Clostridium) difficile (C. difficile)*, an organism that elicits a vigorous neutrophil response. Leukemoid reactions may be associated with solid tumors, sometimes due to paraneoplastic production of colony-stimulating factor (e.g., granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]) or other cytokines (e.g., interleukin [IL]-6 or IL-17), or due to particularly aggressive tumors with necrotic areas. The course of neutrophilia usually correlates with the course of solid cancer. The use of hematopoietic growth factors in cancer patients, cardiopulmonary distress, tissue ischemia such as bowel obstruction, gastrointestinal bleeding, major operations, pancreatitis, or splenectomy are other causes of leukemoid reaction.[1] It is important to quickly differentiate a reactive neutrophilic leukocytosis from a clonal leukemic proliferation. The history and clinical context are usually quite different between leukemoid reaction and CML. Most patients with leukemoid reaction are encountered very ill in the hospital with obvious underlying illnesses (e.g., sepsis, organ rejection). Prior WBC counts, which are often available, demonstrate normal WBC counts until the recent onset of acute illness. This contrasts with CML, typically presenting in outpatients with hypermetabolism (weight loss, sweats, low-grade fever), symptoms referable to splenomegaly, or frequently asymptomatic. On physical examination, the spleen is palpable (occasionally massive) in the great majority of patients with CML, but splenomegaly is unusual with leukemoid reaction in the absence of comorbidities such as liver disease.

Laboratory findings reliably differentiate CML from leukemoid reaction. The total leukocyte count is commonly extremely high with CML (median 100,000/mm^3 in past series), but counts above 100,000/mm^3 are rare and above 150,000/mm^3 virtually unheard of with leukemoid reaction. Circulating myelocytes and even a few blasts are more typical of CML, but may be seen in both disorders. Similarly, changes in platelet number and morphology can be seen with both but are more characteristic of CML (especially when changes are extreme). RBC changes do not reliably separate the disorders except in a few cases with prominent teardrops, which point toward MPN. More helpful is the leukocyte differential: patients with CML almost always have some degree of absolute basophilia and eosinophilia, but infection and glucocorticoid excess induce eosinopenia. (When the leukocyte count is 100,000/mm^3, realize that 2% to 3% basophils is a substantial absolute increase.)

The leukocyte alkaline phosphatase (LAP) score, high with leukemoid reaction and classically low with CML, has limited utility now that there are more sensitive and specific tests for CML. When CML is reasonably considered, testing should be done for the Philadelphia chromosome, t(9;22)(q34;q11.2) by chromosome G-banding, or *BCR–ABL1* fusion product by fluorescence in situ hybridization or reverse-transcriptase polymerase chain reaction. When other MPNs are judged reasonably possible, *JAK2* V617F mutational status may be informative. In cases with very high suspicion for MPNs but negative *JAK2* V617F mutation, *JAK2* exon 12, *MPL*, and *CALR* mutations can be assessed in a serial manner.

Infection

To protect against the ever-present threats to health and longevity, evolution has armed us with reactant cytokine cascades designed to increase the number of phagocytes and dispatch them to threatened locales. Neutrophilia is classically seen as a response to bacterial infection, responding to such cytokines as IL-6, tumor necrosis factor (TNF), and G-CSF. Neutrophilia is also a frequent response to other types of infections, such as fungal, parasitic, mycobacterial, and sometimes viral.

C. difficile infection should be suspected when unexplained neutrophilia is encountered in a patient with diarrhea and abdominal distension, especially with a history of recent use of antibiotics. Two large clostridial glucosylating toxins, toxin A (TcdA) and toxin B (TcdB), are primarily responsible for the colonic epithelial damage and death.[2] These toxins also stimulate epithelial cells and tissue-resident immune cells (macrophages, dendritic cells, and mast cells) to secrete proinflammatory cytokines and neutrophil chemoattractants which recruit neutrophils and result in inflammation.

Changes in neutrophil morphology may be useful in predicting whether bacterial or other infection underlie a neutrophilic response. The authors have confirmed some published reports that prominent neutrophil vacuolization (Fig. 49.3) is highly specific and moderately sensitive for serious bacterial infection, as are prominent Döhle bodies (in the absence of a primary hematologic disorder). The authors blindly assessed 125 blood smears from 50 from patients with serious bacterial infection (half bacteremic), 25 with influenza, 25 with noninfectious fever, and 25 controls. Toxic granulation of neutrophils, touted as a sign of bacterial infection, was found useless in distinguishing infections from other febrile illnesses.[3]

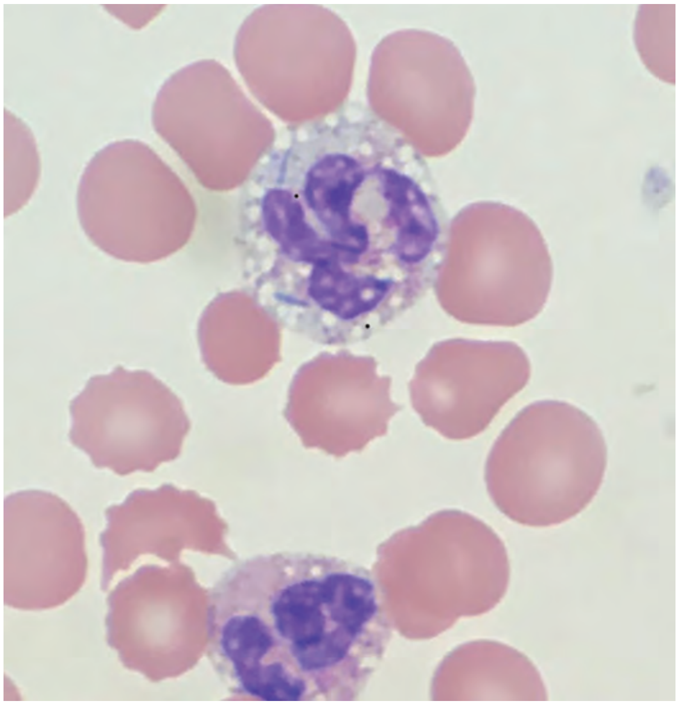

Figure 49.3 VACUOLATED NEUTROPHILS. Strong association with severe bacterial infection/bacteremia.

Inflammation and Stress

Acute or chronic inflammation can cause neutrophilia by mechanisms similar to infection, mediated by the proinflammatory cytokines G-CSF, GM-CSF, TNF, IL-1, IL-6, IL-8, and others. Diseases such as rheumatoid arthritis (RA), vasculitis, inflammatory bowel disease, thyrotoxicosis, eclampsia, and many others are commonly accompanied by neutrophilia. Another rare but notable example is Familial Mediterranean Fever, in which an inherited *MEFV* mutation leads to dysfunctional pyrin and an autoinflammatory disorder with recurrent inflammatory serositis and secondary (AA) amyloidosis.

Physiologic stresses, including exercise and emotional stress, lead to endogenous catecholamine and glucocorticoid release in addition to inflammatory cytokines. This causes a rapid doubling of circulating neutrophils caused by demargination and by more rapid BM egress of maturing neutrophils. Paulsen found early peaks in M-CSF, growth hormone, and cortisol after exercise followed by increases in G-CSF, IL-6, and monocyte chemoattractant protein 1.[4] Acute hemorrhage and hemolytic anemia are other physiologic stresses. This contributes to increased steady-state neutrophil counts recorded in patients with sickle cell anemia, and the degree of elevation correlates with pain crisis frequency, other complications, and mortality; leukocyte reduction has been postulated to be one mechanism of hydroxyurea's beneficial actions. The stress of acute myocardial infarction is commonly accompanied by mild neutrophilia, and the early magnitude of rise has correlated with poor outcomes.

Patients with severe asthma have neutrophil-predominant lung inflammation due to formation of neutrophil extracellular traps (NETosis) and enucleated neutrophil cytoplasts, which in turn lead to T helper 17-mediated neutrophilic inflammation.[5]

Hereditary and Congenital Neutrophilias

In newborns, neutrophilia and leukoerythroblastosis are among the hematologic abnormalities associated with trisomy 13, trisomy 18, and trisomy 21 (Down syndrome). A transient clonal MPN can be seen in children with Down syndrome and is usually self-limited, but it does put patients at increased risk for later acute megakaryoblastic leukemia.

Very rare hereditary neutrophilias are sometimes first appreciated in adults. In 1971, Herring reported a mother and three of her four children with lifelong neutrophilia (WBC: 14,000/mm^3 to 164,000/mm^3; granulocytes: 9000/mm^3 to 62,000/mm^3), unusual bleeding, thickened calvariae, and hepatosplenomegaly. They had no increase in infections. The LAP score was high, BM revealed few Gaucher-like histiocytes, karyotype was normal by routine G-banding, but chromatid breaks and gaps were increased. In 2009, French investigators identified a mutation in the *CSF3R* gene in a kindred with hereditary chronic neutrophilia.[6] The point mutation led to constitutive activation of the G-CSF receptor, driving neutrophil proliferation and differentiation. One of 12 affected individuals in this kindred developed overt myelodysplastic syndrome (MDS). The frequency of this and other mutations are unknown with hereditary neutrophilias.

Smoking

Smoking has been well associated with mild neutrophilia in epidemiologic and animal studies. Perry et al. found a 27% higher WBC count in smokers. Sunyer et al. correlated the degree of leukocytosis and percentage of neutrophils with the number of cigarettes smoked. The effect can persist up to 5 years in those who stop smoking. A suggested mechanism is chronic inflammation because inflammatory markers, including C-reactive protein (CRP) and fibrinogen, are elevated. In a rodent model, cigarette smoke caused overexpression of hematopoietic growth factor genes IL-6, G-CSF, and GM-CSF. Thus, mild neutrophilia without other symptoms in a smoker could be attributed to this practice without further evaluation.

Drugs

Systemic glucocorticoids cause neutrophilia mainly by interfering with neutrophil adhesion to the capillary wall and decreasing neutrophil turnover rate. Maximal neutrophil counts occur 4 to 6 hours after dexamethasone use in normal volunteers. G-CSF increases circulating neutrophils by increasing BM production and mobilization. Epinephrine increases proinflammatory cytokines and demargination. Suggested mechanisms for lithium-induced neutrophilia are induction of G-CSF and downregulation of CXCR4 chemokine receptor, thus facilitating egress from the BM.

Malignancy

Leukocytosis is frequently associated with solid tumors without direct BM involvement. Some malignant tumors have been reported to produce G-CSF or GM-CSF, occasionally producing leukocytosis in the range of a leukemoid reaction. Recent epidemiological studies suggested that the presence of pre-treatment neutrophilia is an independent adverse prognostic factor in patients with advanced solid cancers.[7]

Asplenia

Whereas neutrophilia is classically observed early after splenectomy, lymphocytosis predominates in the long run. Nevertheless, chronic mild neutrophilia can also be seen in functionally asplenic individuals. Furthermore, there may be an exaggerated neutrophil response to infections or other stresses. On the blood smear, Howell–Jolly bodies are a very sensitive and specific (when numerous) sign of functional asplenia.

Obesity

Chronic mild neutrophilia has been observed with obesity.[8] Fat tissue can release inflammatory cytokines, creating a state of low-grade inflammation manifest by elevated CRP. Leptin, a hormone released by adipocytes, may act on CD34$^+$ cells to promote neutrophil differentiation. Chronically inflamed visceral adipose tissue in obesity has been shown to stimulate BM hematopoietic progenitor cells to proliferate and expand, causing both neutrophilia and monocytosis via IL-1β.[9] In an obese patient with chronic mild neutrophilia and no obvious other underlying disorder, this can be assumed to be the cause.

Alcoholic Liver Disease

While excessive alcohol use has been classically associated with neutropenia due to BM suppression, Cai et al. found that some patients with chronic excessive alcohol use may develop neutrophilia and hepatic neutrophil infiltration.[10] Alcohol consumption may cause increased levels of circulating and tissue neutrophil chemotaxin, such as IL-8 or CXCL1, which in turn recruits neutrophils to liver and increases circulating neutrophils. Alcohol also induces hepatic endoplasmic reticulum stress and release of mitochondrial DNA-enriched microparticle into circulation, leading to systematic inflammatory response. In these patients, signs of liver injury, such as elevated serum transaminases, are frequently observed. Therefore, history of excessive alcohol use with elevated liver function tests should raise a suspicion for alcohol being a contributing factor for neutrophilia.

NEUTROPENIA (AND AGRANULOCYTOSIS)

The risk of neutropenia-related infection begins to rise at an ANC near 1000/mm^3, rising dramatically below 500/mm^3 and more so below 100/mm^3; thus, an ANC of 500/mm^3 to 1000/mm^3 is considered moderate neutropenia, and below 500/mm^3 is considered severe. This corresponds to National Cancer Institute criteria for medication adverse hematologic event reporting: grade 1 toxicity is 1500/mm^3 to lower limit of normal, grade 2 is 1000/mm^3 to 1500/mm^3, grade 3 is 500/mm^3 to 1000/mm^3, and grade 4 is less than 500/mm^3. Beyond the ANC, the risk for infection is greatly influenced by the nature of the underlying problem, the BM myeloid reserve, and whether other risk factors for infection are present (e.g., immunoglobulin deficiency or breaks in mucosal barriers). The course with mild and moderate neutropenia is often benign.

The history focuses on the severity and duration of neutropenia, whether infectious complications have occurred (including stomatitis or gingivitis), and whether prior blood counts can be obtained. A history of drug exposures and their timing is especially relevant, not only for prescribed medications but also for over-the-counter, herbal, and illicit drugs. Symptoms of systemic inflammatory illness, such as arthritis, skin rash, and photosensitivity, can bear on the etiology and significance of the low WBC count. Fevers, weight loss, and sweats could be clues to many disorders, including malignancy. Liver disorders commonly present with cytopenias, so a history of hepatitis, jaundice, and HIV risk factors should be specifically sought. Symptoms of anemia or bleeding could be clues to more general hematologic disorders. As with most hematologic problems, physical examination should devote careful attention to lymph node areas and the spleen. Oropharynx and skin examination also take on added importance.

Peripheral blood smear review is irreplaceable to direct the workup. MDS does not characteristically present with isolated neutropenia, but this occasionally is the predominant presenting feature in this relatively common syndrome affecting older patients. Specific blood smear findings which could suggest MDS include pseudo-Pelger–Huet neutrophils (Fig. 49.4), hypogranularity, Döhle bodies (Fig. 49.5), and macrocytic and/or dimorphic RBCs with a hypochromic population. Megaloblastic processes, such as vitamin B_{12} and folic acid deficiency, similarly do not characteristically present with isolated neutropenia, but this occasionally predominates (especially in the presence of acute infection). Hypersegmentation of neutrophils is always present with megaloblastic processes, including those that are drug-induced (e.g., methotrexate, hydroxyurea). Hypersegmented neutrophils (Fig. 49.6) are also seen with uremia, MDS, and MPN. In a neutropenic patient, one should always specifically look for large granular lymphocytes (LGLs) (Fig. 49.7). A modest increase could indicate a reactive T-cell or natural killer (NK) cell process, and a more dramatic increase could alert to clonal T-NK or NK cell proliferations (LGL leukemia). Hairy cells (Fig. 49.8), other morphologic types of circulating lymphoma

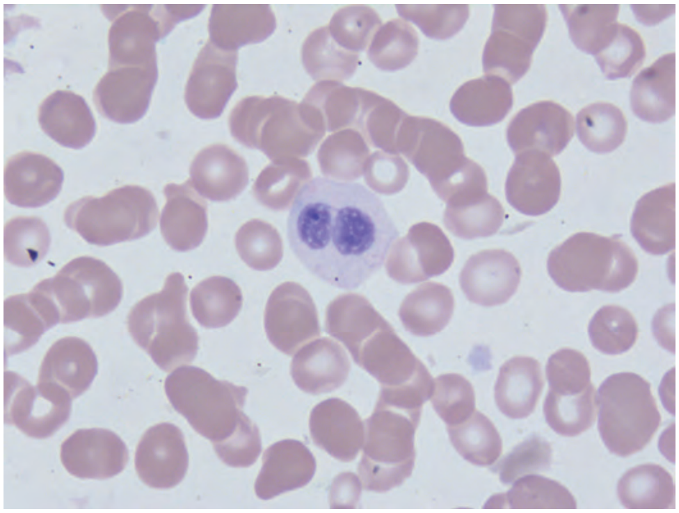

Figure 49.4 PELGER-HUET ANOMALY. (Two symmetric round or oval nuclear lobes connected by a thin strand of chromatin.) Hereditary form (involving almost all neutrophils) is benign. Acquired form suggests MDS (as in this hypogranular example), but may be seen transiently with infection, advanced MPNs, myxedema, others. *MPNs*, Myeloproliferative neoplasms; *MDS*, myelodysplastic syndrome.

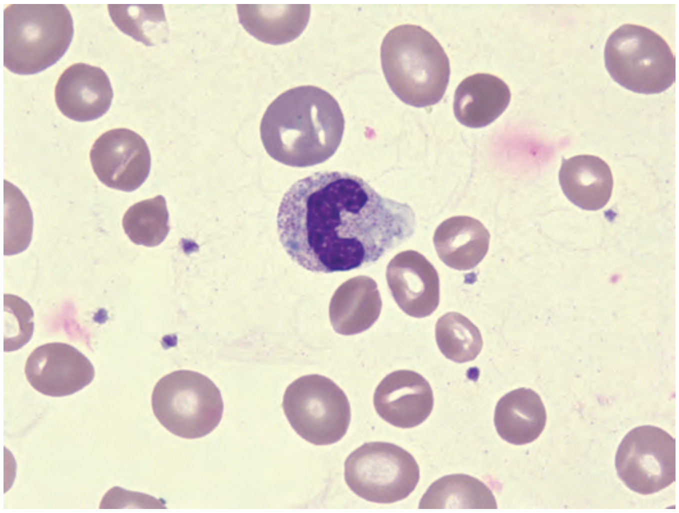

Figure 49.5 DÖHLE BODIES. Most commonly due to infection; myriad other causes include drug-induced (including growth factors), congenital (including MYH9 disorders), MDS. *MDS*, Myelodysplastic syndrome.

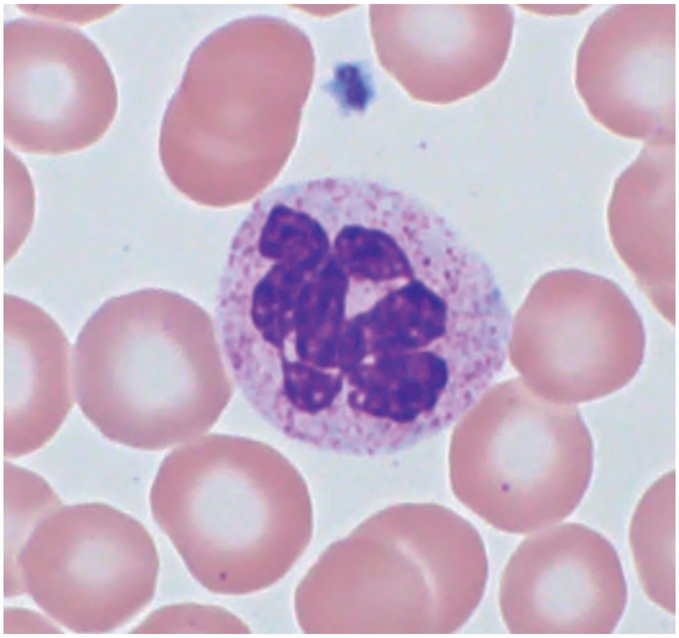

Figure 49.6 HYPERSEGMENTED NEUTROPHIL. Victor Herbert established that hypersegmentation exists if 5% of neutrophils have five lobes or if one has six lobes. This is a sensitive finding for megaloblastic processes (including drug-induced). It is commonly seen with uremia and can be a congenital polymorphism.

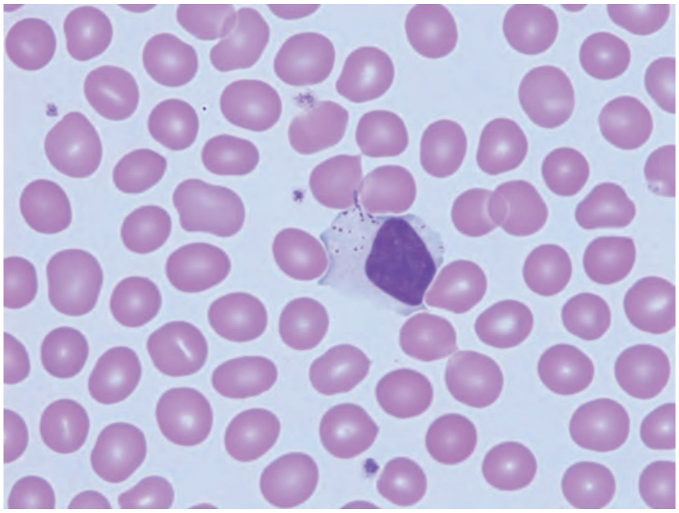

Figure 49.7 LARGE GRANULAR LYMPHOCYTES. (See Chapter 50.) T-NK lymphocytosis can be reactive or clonal, and are associated with cytopenias, especially neutropenia. *NK*, Natural killer.

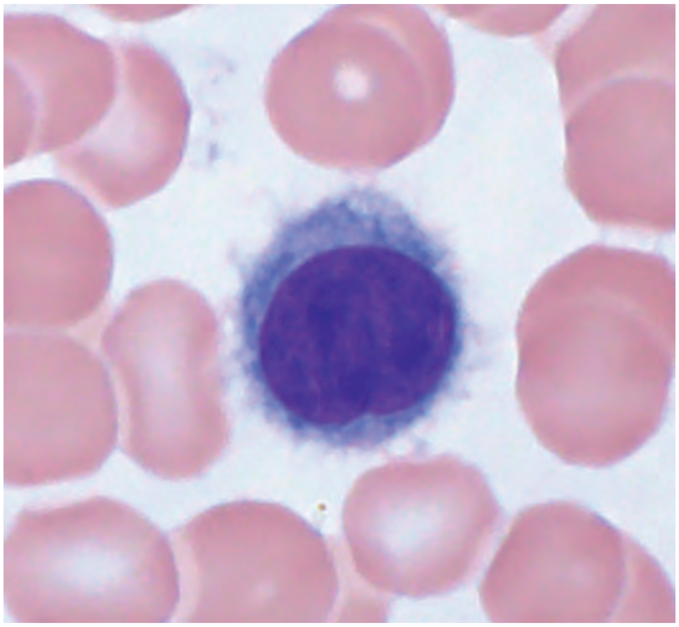

Figure 49.8 HAIRY CELLS. (See Chapter 77.) Hairy cell leukemia is associated with cytopenias, including monocytopenia (in the typical form).

cells, and blasts are obvious indicators of hematologic malignancy. Morphologic suspicions for such processes could be confirmed by flow cytometry. Reactive lymphocytes may suggest viral infection but also occur with drug reactions and other processes.

Further laboratory testing in patients with neutropenia may often be unnecessary. Especially in mild or moderate cases, the lack of specific diagnostic tests has created some overlap and confusion among what have been called *chronic idiopathic neutropenia*, *chronic benign neutropenia*, *ethnic neutropenia*, and *autoimmune neutropenia*. Autoimmune neutropenia is a relatively common cause of both mild and more severe neutropenia, but tests for antineutrophil antibodies are not clinically reliable (see later). Serologic tests for antinuclear antibodies and rheumatoid factor can be helpful when autoimmune neutropenia is considered, as positive results may raise suspicion for an undiagnosed collagen vascular disorder or may just support a less specific autoimmune problem. Direct antiglobulin test and antiphospholipid antibodies can also be supportive when there is suspicion for an autoimmune process. Quantitative immunoglobulin levels may reveal an underlying immunodeficiency when there is evidence of autoimmunity or when infectious complications are disproportionate. Serologic tests for some viral infections (HIV, hepatitis, Epstein-Barr virus [EBV]) may sometimes be appropriate. The main utility of flow cytometry occurs when peripheral blood smear suggests an abnormal lymphocyte population (e.g., LGLs or hairy cells). Because LGL leukemia is a relatively common cause of significant neutropenia and because this is a diagnosis frequently initially missed, one should have a low threshold to obtain flow cytometry, assuring that proper markers are analyzed (see later). BM examination may not be helpful or warranted with mild or even moderate isolated neutropenia or in straightforward cases of severe neutropenia (e.g., after drug exposure), but can be essential when the diagnosis is in doubt and especially if other cell lines are compromised.

Severe Congenital Neutropenias

It is beyond the scope of this chapter to review in detail the heterogeneous genetic disorders that manifest in early childhood as severe congenital neutropenia (SCN); nevertheless, consultant hematologists should have some familiarity with this problem both because modern therapy has extended survival for many into adulthood, and because milder forms of these disorders may go undiagnosed until young adulthood. More severe forms of SCN present in infancy with severe stomatitis and recurrent bacterial infections. The molecular bases have been greatly elucidated, among them: (1) an autosomal dominant mutation of the neutrophil elastase gene *ELANE* in 50% to 60% of patients, (2) an autosomal recessive mutation of *HAX1*, which is associated with mental retardation and other congenital defects found in Kostmann syndrome, (3) the other genes account for only a small proportion of all cases: *G6PC3*, *GF11*, *CSF3R*, *WAS* (X-linked), *CXCR4*, *VPS45A* and *JAGN1*, and (4) about one-third of patients do not have identifiable mutations in the above-mentioned genes.[11]

In young children, the differential diagnosis of SCN includes transient postinfectious neutropenia, alloimmune neutropenia, or hematologic malignancy. BM examination often shows a pattern of maturation arrest (Fig. 49.9). The majority of affected patients are responsive to G-CSF, which has favorably impacted infectious morbidity and mortality. Allogeneic stem cell transplant is another therapeutic option. An intrinsic risk of acute myeloid leukemic transformation, 15% at 20 years, accompanies these disorders, with higher risk in those requiring higher doses and/or responding poorly to G-CSF.

Cyclic neutropenia is a rare autosomal dominant disorder with variable expression, also caused by autosomal dominant mutations of *ELANE* or rarely its transcription regulator. Neutrophil counts vary from mildly to severely low with predictable periodicity, usually about 21 days. The great majority of cases are responsive to G-CSF at low dosage.

Warts, Hypogammaglobulinemia, Infections, and Myelokathexis Syndrome

WHIM syndrome is a rare autosomal dominant immunodeficiency with **W**arts, **H**ypogammaglobulinemia, **I**nfections, and **M**yelokathexis. It is due to heterozygous gain-of-function mutations in the chemokine receptor, *CXCR4*.[12] CXCR4 is expressed on hematopoietic progenitor cells and regulates homing to BM where the ligand of CXCR4, CXCR12 (also known as SDF-1), is abundantly expressed. In WHIM syndrome, mutant *CXCR4* prolongs interaction with CXCR12 and causes excessive marrow retention of neutrophils and other leukocytes. The diagnosis is made based on DNA sequencing for relevant mutations in *CXCR4*. Treatment includes G-CSF (titrate to the lowest possible dose to achieve an ANC between 1000 and 2000/mm^3) and more recently, CXCR4 antagonists, such as plerixafor or mavorixafor, have been used with success.

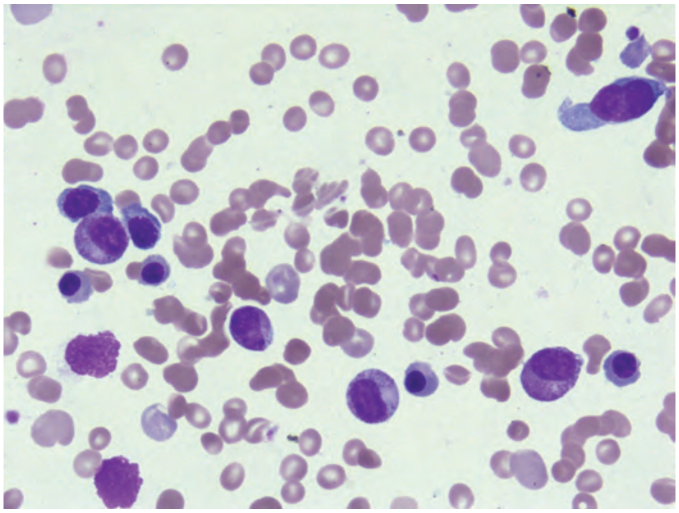

Figure 49.9 MATURATION ARREST (bone marrow aspirate). (Almost no myeloid precursors beyond myelocyte [sometimes promyelocyte] stage.) Non-specific: can be seen with early precursor release, early recovery from myelosuppression, peripheral destruction (including antibody-mediated), and stem cell disorders.

Shwachman-Diamond syndrome is an inherited BM failure disorder due to biallelic pathogenic variants in *SBDS*, *EFL1*, or *SBDS*, or a heterozygous pathogenic variant in *DNAJC21*.[13] Neutropenia is the most common presenting cytopenia, but bilineage or trilineage cytopenia can occur. Patients have hypocellular BM and characteristic exocrine pancreatic dysfunction manifesting as diarrhea or failure to thrive. Positive family history and other constitutional abnormalities, such as short stature and skeletal malformation, can point toward this diagnosis. About 15% to 20% of patients progress to MDS/AML by the age of 20. Hematopoietic stem cell transplantation should be considered for progressive BM failure or MDS/AML.

Lower Neutrophil Count With Fy(a-b-) Status (Previously Known as Benign Ethnic Neutropenia)

Individuals of African descent may have chronic mild neutropenia not associated with infectious complications. The 1999 to 2004 National Health and Nutrition Survey found that Black individuals had mean leukocyte counts 900/mm^3 lower than White individuals, with ANCs below 1500/mm^3 in 4.5% (compared with 0.8% of White individuals).[14] Low ANC is correlated with homozygosity of a single nucleotide polymorphism in the gene Duffy antigen receptor for chemokines (*DARC*; also known as *ACKR1*; rs2814778), which results in the absence of Duffy antigen from RBCs (termed Duffy null or Fy(a-b-)). The Fy(a-b-) phenotype is commonly found in individuals from sub-Saharan African and Arab, but rare in White European or Asian ancestry.[15] BM biopsies performed for isolated low ANC in the setting of the Fy(a-b-) genotype rarely reveal abnormalities.[16] Thus, an asymptomatic mildly neutropenic person without abnormalities on blood smear who carries the Fy(a-b-) genotype may require no further diagnostic workup. It may be reassuring to the patient (and the doctor) if prior blood counts can be retrieved to document the chronic, nonprogressive, and complication-free course of the neutropenia.

Autoimmune Neutropenia (Primary and Secondary)

Autoimmune neutropenia can be primary or secondary to an autoimmune disorder such as SLE or RA.[17] Neutropenia can be mild or severe. Classically, it is caused by antineutrophil autoantibodies, although autoreactive cytotoxic lymphocytes may also cause this problem. When performed, BM examination often is normocellular or hypercellular, with a late "maturation arrest" picture. Severe cases can display pure WBC aplasia (similar to drug-induced agranulocytosis, which may sometimes also be antibody-mediated). There are several challenges to making the diagnosis. One is that the maturation arrest BM picture is very nonspecific with regard to mechanism: it could indicate a true stem cell differentiation defect, or the early release of later precursors (as with sepsis or splenic sequestration), or an immune attack aimed at antigens on later myeloid precursors, or early recovery from a toxic insult. Another problem is the lack of clinically reliable neutrophil antibody tests. Experimentally, several methods have been used, generally suffering from high false-negative and false-positive rates in detecting antibodies against neutrophil antigens or immune complexes that bind to neutrophil Fc receptors. With no definitive test, diagnosing autoimmune neutropenia rests largely on clinical context and judgment.

Neutropenia caused by antineutrophil antibodies has been seen in infants about 1 year old, usually running a benign clinical course with spontaneous remission in 95% within 2 years. Newborns are at risk of alloimmune neutropenia in the first months of life, but this is not generally accompanied by infectious complications. Secondary autoimmune neutropenias are most common in adults, related to disorders such as SLE, RA, Sjögren syndrome, thymoma, and common variable immunodeficiency. In SLE, neutrophil counts correlate with disease activity and have been related to the induction of TNF–related apoptosis-inducing ligand (TRAIL), a ligand that increases myeloid apoptosis and killing by autologous T cells. Immunosuppressive therapy of the SLE or the use of G-CSF can improve the WBC count.

Felty syndrome was classically described as severe neutropenia and splenomegaly complicating RA, and has been attributed to antineutrophil antibodies, but the distinction between this syndrome and other causes of neutropenia with RA have become blurred. In particular, classic Felty syndrome and LGL syndrome appear to represent points on a disease continuum. About 1% of patients with RA develop Felty syndrome, and it predisposes many to serious infections. Effective therapies have often included methotrexate, gold salts, and rituximab. Because of some risk of exacerbating underlying inflammatory problems, G-CSF should be used with caution.

Large Granular Lymphocyte Leukemia

LGL leukemias are covered elsewhere, but mention is required here because these are common considerations in adults with neutropenia. LGL leukemia is a chronic lymphoproliferative disorder due to clonal expansion of cytotoxic T or NK LGLs. The expansion of cytotoxic effector cells are due to chronic antigen-driven immune stimulation and therefore treatment is based on immunosuppression. These proliferations are frequently associated with autoimmune disorders (especially RA), variable degrees of neutropenia, anemia, commonly splenomegaly, and increased infectious risks. The diagnosis is suggested on blood smear by large lymphocytes with mature chromatin, excessive cytoplasm, with or sometimes without prominent cytoplasmic granules. Flow cytometry demonstrates increased $CD3^+CD57^+$ lymphocytes with the more common T-LGL proliferations or may show $CD3^-$ $CD56^+$ clones with "pure" NK cell LGL proliferation. Clonality can be established by T cell receptor (TCR) repertoire analysis by PCR. Killer cell immunoglobulin-like receptor (KIR) repertoire analysis by flow cytometry is used to determine clonality in NK-LGL. Somatic activating mutations in the signal transducer and activator of transcription 3 gene (STAT3) were found in 40% of patients with LGL leukemia, suggesting aberrant STAT3 signaling pathway is an underlying mechanism of this disease.[18] Somatic activating STAT5b mutations were also found in a minority of patients.[19]

Neutropenia With Infectious Diseases

Leukocytosis is the expected response to most bacterial infections, but leukopenia also occurs and is characteristic of infection by certain organisms. Viral infections often cause transient mild leukopenia, so restraint is wise in the diagnostic approach to a newly recognized moderate leukopenia in a febrile, modestly ill patient. Nonbacterial infections in which neutropenia is frequent or even characteristic include HIV, EBV, cytomegalovirus (CMV), hepatitis A and B, measles, rubella, varicella, rickettsia, and anaplasmosis (ehrlichiosis). Bacterial infections with characteristic leukopenia include typhoid fever and brucellosis, and granulomatous infections (tuberculosis, histoplasmosis [Fig. 49.10] also commonly cause neutropenia, especially when the BM is directly involved. In patients with poor BM reserve (e.g., prior chemotherapy, malnutrition, myelodysplasia), an acute infection very often lowers, rather than raises, the neutrophil count. Profound neutropenia is a known consequence of overwhelming sepsis and has been associated with poor outcomes.

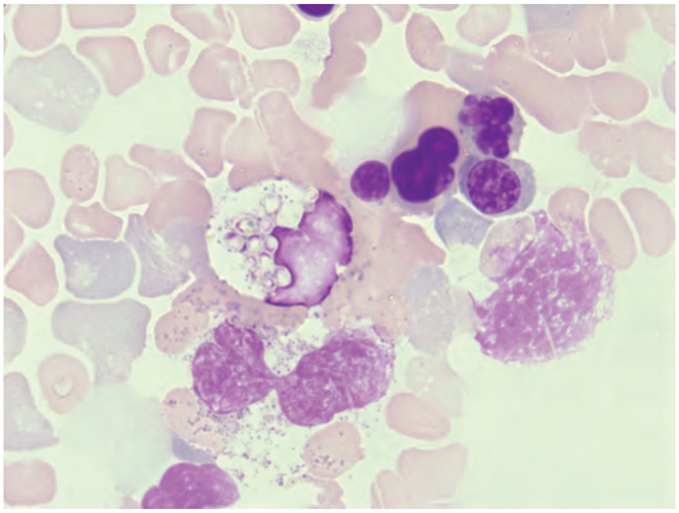

Figure 49.10 HISTOPLASMOSIS. In disseminated histoplasmosis, organisms can frequently be seen in leukocytes and histiocytes in bone marrow and sometimes peripheral blood.

Hypersplenism

Hematologists are frequently consulted for cytopenias, only to find an unappreciated large spleen as the etiology (this is most commonly due to liver disease with portal hypertension). Splenic enlargement can lead to sequestration and reduction of circulating WBCs, RBCs, platelets, or any combination of these. The degree of cytopenia is somewhat proportional to the degree of splenic enlargement. Substantial neutropenia out of proportion to the depletion of other cell lines and to the degree of splenomegaly suggests an autoimmune component (which can be seen with hepatitis C or autoimmune hepatitis) or medication effect (e.g., interferon).

Chemotherapy-Induced Neutropenia

The major dose-limiting toxicity of most cancer chemotherapy regimens is neutropenia. This results in hospitalizations, antibiotic costs, reduced quality of life, infectious morbidity, dose reductions, and treatment delays that compromise efficacy and outcomes, and result in some deaths: 75% of chemotherapy-related mortality. Febrile neutropenia is defined as an ANC less than $500/mm^3$ (or expected to decrease to $<500/mm^3$ over the next 48 hours) with fever ($>38.3°C$ or sustained $>38°C$).

Principles of empiric antibiotic coverage for acute febrile episodes in severely neutropenic patients are covered in detail elsewhere. Basically, there is a high risk of sepsis (even when the source is occult), and a favorable outcome depends on prompt effective antimicrobial coverage, so empiric administration of broad-spectrum antibacterial agents is considered medically emergent. There must be coverage of the traditional aerobic gram-negative rod culprits (particularly *Pseudomonas*), yet vigilance must be maintained for the Gram-positive organisms that have emerged as major pathogens. With prolonged or repeated episodes of neutropenia, invasive fungi become common threats to survival, particularly *Aspergillus*, *Candida*, *Mucor*, and *Fusarium* spp. Published guidelines can aid the choice of empiric antimicrobials. Because of difficulty demonstrating favorable impact, enthusiasm for granulocyte transfusions has waned in the past 30 years.

The utility of prophylactic antibiotics is problematic because of the wide array of potential pathogens and because of concerns of inducing antibiotic resistance. Prophylactic fluoroquinolones, antifungals, and antivirals have had some favorable impact in very high-risk patients after consolidation therapy for acute leukemia or allogeneic stem cell transplant.[20]

G-CSF or pegfilgrastim is widely used for primary or secondary prevention of neutropenia to decrease morbidity and mortality of febrile neutropenia. Primary prophylaxis is recommended by various guidelines if the risk of developing febrile neutropenia is greater than 20%.[21] This risk is calculated from age, extent of primary cancer, comorbidities, and the known myelotoxicity of the chemotherapy regimen. G-CSF is begun 24 to 72 hours after the completion of myelotoxic chemotherapy.

Drug-Induced Neutropenia

Drug reactions account for a high percentage of acquired neutropenia, both mild but, more so, severe cases (agranulocytosis; Table 49.2). Neutropenia often develops abruptly, within 4 weeks of initiation of a causative agent. Pathophysiology may involve immune mechanisms or more direct toxicity such as enhancement of reactive oxygen species made by nicotinamide adenine dinucleotide phosphate oxidase or myeloperoxidase on neutrophil precursors.[22] They can be strongly suspected from an accurate history that plots leukocyte numbers against the time course of drug exposure; confirmation is leukocyte recovery after drug withdrawal. More specific confirmatory testing, such as drug-dependent antibodies, is mainly an area of research laboratory investigation. BM examination is not usually required but may be helpful when pathophysiology and diagnosis are in doubt, when the course is atypical, and to provide prognostic information (earlier recovery may be anticipated with a picture of "maturation arrest" than that of myeloid aplasia). Treatment demands discontinuation of suspected offending drugs. Although the efficacy of myeloid growth factors (G-CSF) has been questioned, most recommend this therapy because even a modest shortening of severe neutropenia can occasionally be lifesaving. Mortality of drug-induced agranulocytosis is generally reported to be 10%.

The most commonly implicated drugs are listed in Table 49.2. Some merit additional comment. Some drugs have a direct myelotoxic effect rather than induce an idiosyncratic immune-based reaction. Neutropenia will have more gradual onset related to dose and duration, and may be accompanied by suppression of other hematologic cell lines. Linezolid and most instances of chloramphenicol myelosuppression are examples.

Beginning 2007, an epidemic of agranulocytosis was found among intravenous cocaine users. The adulterant levamisole was found in 71% of confiscated cocaine by the Drug Enforcement Agency, with the incidence of agranulocytosis 2.5% to 13% in those exposed. Nadir BM showed severe myeloid hypoplasia. Levamisole had long been linked to agranulocytosis, having been used as an antihelminth and as an immune adjuvant in patients with autoimmune disorders and colorectal cancer.

Severe neutropenia is seen in patients treated with rituximab.[23] This neutropenia is unusual for its late onset, generally about 3 months after the last rituximab dose. It occurs with underlying autoimmune disorders, B-cell malignancies, and stem cell transplants—basically in all situations in which rituximab is used—often occurring while the underlying illness is in complete remission. Severe neutropenia has been reported in about 5% of rituximab-treated patients, much higher in some series. Most patients recover quickly, usually after G-CSF therapy, but there have been protracted cases. The authors and others have reported a high risk of relapse (100% in our series) if rituximab is reinitiated. The mechanism is not definitively established, but an intriguing report implicates imbalanced recovery of B-cell clones with a deficiency of stromal-derived factor 1.

Immunotherapy-induced severe neutropenia has been reported in individuals with pre-existing autoimmune disorders.

MONOCYTOSIS

Monocytosis is extremely nonspecific, usually not requiring investigation per se. Monocytosis has been defined as a sustained absolute increase in monocyte count greater than $800/mm^3$ to $1000/mm^3$ (Table 49.3). Transient monocytosis, relative or absolute, is common with recovery from myelosuppression, such as after chemotherapy. Relative or absolute monocytosis may occur in other myelosuppressed states, such as aplastic anemia. This is a favorable factor associated with a lower risk of neutropenic infection, perhaps because some phagocytic capacity is maintained. On the other hand, monocytosis is also very common with hematologic malignancies. In a patient with unexplained cytopenia, monocytosis can be an important clue to an underlying MDS/MPN.

Infectious Diseases

Mycobacterial infection is a common cause of monocytosis worldwide, related to its propensity for intracellular infection and tissue granuloma formation. Brucellosis and subacute bacterial endocarditis have also been associated with monocytosis. Certain viral infections, including influenza, varicella-zoster, CMV, and dengue, have been reported to cause monocytosis.

TABLE 49.2 **Drugs Commonly Associated With Neutropenia**

1. Antibiotics: vancomycin, semisynthetic penicillins, chloramphenicol, sulfa, linezolid
2. Antithyroid drugs: methimazole, propylthiouracil
3. Cardiovascular: ticlopidine, procainamide
4. Antipsychotics: clozapine, olanzapine, chlorpromazine
5. Anticonvulsants: phenytoin, carbamazepine, valproic acid
6. Antiinflammatory agents: indomethacin, sulfasalazine, phenylbutazone
7. H2 blockers: cimetidine, ranitidine
8. Analgesics: dipyrone
9. Antineoplastic: rituximab
10. Anthelmintic: levamisole

TABLE 49.3 **Changes in Monocyte Number**

Monocytosis

Infections: tuberculosis, granulomatous infection, brucellosis, subacute bacterial endocarditis
Connective tissue disorder
Recovery from myelosuppression
Hematologic malignancies:
1. MDS, MPN, MDS–MPN overlap (e.g., CMML)
2. Acute and chronic monocytic leukemia, myelomonocytic leukemia
3. Hodgkin and non-Hodgkin lymphomas

Obesity

Monocytopenia

Hairy cell leukemia
GATA2 deficiency (also known as MonoMAC syndrome, DCML, Emberger syndrome, familial MDS/AML)
Aplastic anemia
Drugs: chemotherapy, IFN-α, glucocorticoids (transient)
Radiation therapy

AML, Acute myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *DCML*, dendritic cell, monocyte and lymphoid deficiency; *IFN*, interferon; *MDS*, myelodysplastic syndrome; *monoMAC*, monocytopenia and mycobacterium avium complex syndrome; *MPD*, myeloproliferative disorder; *MPNs*, myeloproliferative neoplasms.

Connective Tissue Disorder

Connective tissue disorders, such as SLE and RA, have been associated with monocytosis in the context of chronic inflammation.

Hematopoietic Malignancies

Monocytosis is common with MDS/MPN. CMML is defined as persistent peripheral blood absolute monocytosis greater than 1000/mm^3 and relative monocytosis in peripheral blood (≥10%), absent Philadelphia chromosome, absent *PDGFRA* and *PDGFRB* rearrangements, less than 20% blasts in peripheral blood and BM, and evidence of dysplasia in one or more hematopoietic cell lineages. Juvenile myelomonocytic leukemia, a disease of children that shares pathologic features with CMML, results from defective RAS signaling. Acute myeloid leukemias (AMLs) involving the monocyte line (acute myelomonocytic and acute monoblastic leukemias) may release substantial amounts of lysozyme (muramidase), which is toxic to renal tubules. Serum lysozyme was used to aid in the diagnosis of these leukemias. Monocytosis can result from other myeloid leukemias, MPNs, and lymphomas, particularly Hodgkin lymphoma.

MONOCYTOPENIA

Monocytopenia frequently accompanies granulocytopenia with chemotherapy, aplastic anemia, or other BM-suppressive insults. Isolated or disproportionate monocytopenia is rarely recognized, but observations suggest that this can have serious clinical sequelae when it occurs. In hairy cell leukemia and monoMAC syndrome (GATA2 deficiency), there is a clear association with severe opportunistic infections, particularly those normally engendering a granulomatous response.

Hairy Cell Leukemia

This disorder, considered in detail elsewhere, classically presents with pancytopenia and splenomegaly, often in middle-aged men. The WBC count is sometimes high because of hairy cell proliferation, but monocytes are invariably severely depressed. (Monocytopenia is not seen with “variant hairy cell leukemia.”) Neutropenia only partly explains the very high infectious morbidity and mortality. An extraordinary incidence of opportunistic granulomatous infections has been encountered, including atypical mycobacteria, tuberculosis, histoplasmosis, and other fungi.[24] These are linked to monocytopenia, with impaired granuloma formation. With remission induced by modern therapies (e.g., cladribine, pentostatin or moxetumomab pasudotox), monocytopenia and infectious risks have been mitigated.

GATA2 Deficiency

In 2010, investigators at the National Institutes of Health and in the UK simultaneously described an immunodeficiency syndrome characterized by decreased or absent monocytes, NK cells, B cells, and dendritic cells; this clinical syndrome was named *MonoMAC* or *dendritic cell, monocyte and lymphoid deficiency*.[25] This was largely diagnosed in young adults (median age: 33 years). All patients have opportunistic infections, particularly *Mycobacterium avium* complex and other mycobacteria, opportunistic fungi, and viruses, particularly human papillomavirus. Both autosomal dominant and sporadic cases are described, all linked to mutations in the hematopoietic stem cell regulator *GATA2*. Heterozygous mutations in *GATA2* are also responsible for Emberger syndrome (primary lymphedema and a predisposition to AML) and familial MDS/AML. BM examination findings are almost always abnormal, usually hypocellular, with increased reticulin fibrosis, multilineage dysplasia with characteristic separated nuclei in megakaryocytes, and absent B and NK precursors. Clonal cytogenetic abnormalities are seen in most patients, particularly monosomy 7 in 16% and trisomy 8 in 24%. Because leukemic progression with or without death from infection is high, stem cell transplantation is recommended when feasible. When a family member is used as a BM donor, *GATA2* sequencing must be performed to rule out asymptomatic carrier status before donating. When monocytopenia out of proportion to neutropenia is detected in a patient with or without human papillomavirus-associated warts or MAC infection, examination of B- and NK-cell count by flow cytometry will be informative. Detailed family history may reveal additional patients with infectious complications or MDS/AML.

CHRONIC MILD NEUTROPHILIC LEUKOCYTOSIS

A 46-year-old man was referred to the hematology clinic for evaluation of neutrophilia that was noted by his primary care physician on a routine blood test. He reported no fevers, chills, or night sweats. He had good energy and was working full time as a lawyer. He denies fatigue, weight loss, or rashes. His past medical history included hypertension and obesity, but he was otherwise healthy. He has been smoking cigarettes for 10 years. Family history was negative for blood diseases. Vital signs were normal. Body mass index was 40.5 kg/m^2. Physical examination revealed only an obese abdomen. Laboratory values showed white blood cell (WBC) 12,500/mm^3, absolute neutrophil count (ANC) 8500/mm^3, Hb 14 g/dL, hematocrit (Hct) 42%, platelets 400 K/mm^3. Chemistries were unremarkable. Peripheral blood smear showed only increased neutrophils, with unremarkable red blood cells (RBCs) and platelets. A complete blood cell count 2 years earlier showed WBC 11,800/mm^3, ANC 8100/mm^3, Hb 14.2 g/dL, platelets 385 K/mm^3. What is the next step in evaluation?

This patient has mild neutrophilia of at least 2 years of duration. Obesity and smoking are common causes of neutrophilia. There is no evidence of chronic infection, inflammation, or hematologic malignancy. No further hematologic evaluation is warranted. We recommend only follow-up and counseling about lifestyle changes.

ACUTE SEVERE NEUTROPHILIC LEUKOCYTOSIS

A 78-year-old woman who was a nursing home resident presented to the emergency department with altered mental status, diarrhea, and abdominal pain. She was recently treated with ciprofloxacin for urinary tract infection. On physical examination, she is difficult to arouse. Vital signs show blood pressure 105/66 mmHg, heart rate 98/min, respiratory rate 18/min, temperature of 100.4°F. Abdominal examination reveals distension, active bowel sounds, no organomegaly. Laboratory findings show white blood cell (WBC) 88,000/mm^3, Hb 10.5 g/dL, platelets 200/mm^3, neutrophils 65%, lymphocytes 5%, monocytes 4%, eosinophils <1%, basophils <1%, bands 25%. Hematology is consulted for the high WBC. Peripheral blood smear shows increased neutrophils, with a few metamyelocytes, and myelocytes. Red blood cells (RBCs) are normocytic and normochromic. Platelets are unremarkable. Records from one month earlier show normal blood counts except mild anemia with a Hb of 10.9 g/dL.

The almost certain cause of the extreme leukocytosis in this patient is leukemoid reaction, perhaps due to urosepsis or *Clostridioides difficile* infection. *C. difficile* is classically associated with severe neutrophilia and recent antibiotic use with diarrhea and abdominal distension. The absence of splenomegaly, eosinophilia, and basophilia, and near normal blood counts a month ago makes chronic myeloid leukemia (CML) or other myeloproliferative neoplasm (MPN) very unlikely. We would recommend appropriate tests, antibiotics, clinical follow-up, but no molecular testing for CML at this time.

CHAPTER 50

LYMPHOCYTOSIS, LYMPHOCYTOPENIA, HYPERGAMMAGLOBULINEMIA, AND HYPOGAMMAGLOBULINEMIA

Sravanti P. Teegavarapu and Martha P. Mims

Any discussion of quantitative abnormalities of lymphocytes and immunoglobulins is necessarily linked because the B-cell compartment is responsible for immunoglobulin production and the T-cell compartment helps to provide the stimulus. Nevertheless, clinicians are often consulted when a quantitative disorder of one or the other is recognized. Thus, although overlapping, the defects are presented separately.

QUANTITATIVE DISORDERS OF LYMPHOCYTES

The normal number and distribution of lymphocyte subtypes in the peripheral blood vary with age, but no careful study has demonstrated gender or ethnic differences in lymphocyte count. In general, circulating T cells exceed B cells by a ratio of approximately four to one, with that ratio increasing slightly with age (Table 50.1). Natural killer (NK) cells are grouped with lymphocytes but comprise only approximately 10% of the lymphocyte population. Infants have total lymphocyte counts between 5500/μL and 7000/μL, but this number declines beginning at approximately 1 year of age to reach 2000/μL to 2400/μL in adults. At birth, the total number of circulating B cells is approximately 1000/μL but decreases over the first 10 years of life to approximately 200/μL to 300/μL by the age of 18 years. A slow decline in circulating B cells continues throughout adulthood and is primarily accounted for by a decline in transitional and naive B cells with a stable or mild increase in circulating memory B-cell numbers with age. Circulating naive B cells represent about two thirds of the entire naive B-cell pool, and circulating memory B cells represent only about one-third of the entire memory B-cell pool.[1]

T cells dominate the circulating lymphocyte population with approximately 3500/μL in infancy, declining to 1500/μL on average in young adults, with even lower numbers (approximately 1200/μL) in elderly adults. In both children and adults, CD4 cells outnumber CD8 cells. Naive CD4 and CD8 T cells decline with age by twofold to fourfold. In one large study, CD4 memory T cells significantly increased with age, but no such trend was seen for CD8 memory T cells.[2]

Against this background, *lymphocytosis* is defined as a lymphocyte count greater than 8000/μL in young children and greater than 4000/μL in teenagers and adults. Lymphocytopenia has been defined as a total lymphocyte count of less than 1000/μL in older children and adults and less than 1500/μL in infants and young children. Given the composition of the circulating lymphocyte pool, it is critically important to define which lymphocyte subsets are overrepresented or underrepresented when there is a quantitative disorder.[2]

Lymphocytosis

As in any clinical disorder, a careful history is critical to defining the origin of lymphocytosis. Inherited causes of lymphocytosis are rare. One recently identified inherited lymphocytosis is BENTA disease (B-cell expansion with nuclear factor kappa-B [NF-κB] and T-cell anergy). Germline gain-of-function mutations in caspase-activating recruitment domain 11 (*CARD11*) drive this disorder, which is characterized by polyclonal lymphocytosis and splenomegaly beginning in infancy. However, in most cases of lymphocytosis, the issue is to determine whether a lymphocyte disorder is clonal/malignant or benign and related to infection, drugs, or physiologic stress. Rarely, neither a malignancy nor an underlying condition can be identified, in which case the lymphocytosis is termed *persistent polyclonal B-cell lymphocytosis* (PPBL). When an excess of B cells exists, clonality can usually be defined by examining cell surface expression of κ- and λ-light chains using antibody techniques; with T-cell proliferation, it may be important to define clonality by examining T-cell receptor gene rearrangement using molecular procedures. In the case of NK cell disorders, clonality can be difficult to determine and often only provided by analysis of chromosomal abnormalities of restriction fragment length polymorphisms of X-linked genes. In general, a restricted flow cytometry pattern of killer immunoglobulin-like receptor (KIR) expression on NK cells is accepted as a surrogate marker of clonality.

Clonal Disorders

Malignant causes of peripheral blood lymphocytosis are covered in Chapters 75, 76, 81, 82, 85, and 88 and include chronic lymphocytic leukemia (CLL), hairy cell leukemia, splenic marginal zone lymphoma, lymphoplasmacytic lymphoma, follicular lymphoma, mantle cell lymphoma, adult T-cell leukemia or lymphoma, and Sézary syndrome. Occasionally, precursor T-cell or precursor B-cell leukemia presents with circulating small cells, which morphologically appear more similar to mature lymphocytes than blasts.

A recently identified clonal disorder causing lymphocytosis is monoclonal B-cell lymphocytosis (MBL), an accumulation of clonal B lymphocytes in the blood that does not meet the criteria for CLL (greater than 5000 clonal B cells/μL) but is nevertheless defined by the presence of a clonal population of B cells. Data demonstrate that up to 10% to 15% of patients with lymphocytosis have MBL. Three major subtypes of MBL exist: the CLL immunophenotype ($CD5^+$, $CD23^+$), which is by far the most common; the atypical CLL type ($CD5^+$, $CD20^+$, $CD23^{+/-}$); and non-CLL lymphoproliferative disorder ($CD5^-$). In a systematic study of blood donors more than 45 years of age, 7.1% had detectable MBL. Of these, the majority had the CLL immunophenotype and more than 93% were low-count MBL (B-cell clonal count less than 500 cells/μL). Similar to the relationship between monoclonal gammopathy of uncertain significance and multiple myeloma, only a small proportion of patients with CLL-type MBL (1% to 4% per year) go on to develop progressive disease requiring treatment. Epidemiologic studies of MBL patients have demonstrated strong familial risk for CLL, and the first reports of MBL came from studies of "unaffected" CLL family members. Studies of CLL families suggest that there is an inherited abnormality that increases the risk of developing CLL, and some families exhibit anticipation, with the disease occurring earlier in successive generations. The supposition that MBL is a progenitor lesion for CLL is strengthened by the observation that both low-count and high-count MBL carry the same cytogenetic aberrations observed in good-prognosis CLL. MBL mutations including SF3B1, BIRC3, DDX3X, CHD2, or NOTCH1 had shorter time-to-treatment and expression of CD38, ZAP-70, and CD49d increased the risk of progression. Only del17p and trisomy 12 were independent predictors of need for treatment. MBL has been identified in up to 30% of individuals infected

TABLE 50.1 **Normal Lymphocyte Subsets With Age**[a]

	Cord Blood	2 Days–11 Months	1–6 Years	7–17 Years	18–70 Years
Total lymphocyte count (×10^3 cells/mL)	5.4 (4.2–6)	4.1 (2.7–5.4)	3.6 (2.9–5.1)	2.4 (2.0–2.7)	2.1 (1.6–2.4)
CD4$^+$ T cells (%)	35 (28–42)	41 (38–50)	37 (30–40)	37 (33–41)	42 (38–46)
CD45Ra$^+$ in CD4$^+$ (naive T cells)[b]	91 (82–97)	81 (66–88)	71 (66–77)	61 (55–67)	40 (32–49)
CD8$^+$ T cells (%)	29 (26–33)	21 (18–25)	29 (25–32)	30 (27–35)	35 (31–40)
B cells (%)	20 (14–23)	23 (19–31)	24 (21–28)	16 (12–22)	13 (11–16)
NK cells (%)	20 (14–30)	11 (8–17)	11 (8–15)	12 (9–16)	14 (10–19)

[a] Values are median, with ranges from the 25th to 75th percentiles.

with hepatitis C virus (HCV), and up to 50% of the HCV-associated cases demonstrate the atypical CLL immunophenotype. The presence of MBL correlates with more advanced liver disease, suggesting that the persistence of viral infection is crucial to development of the B-cell clone. Follow-up for MBL patients is not clearly defined, although it is probably reasonable to have all but low-count CLL-type MBL patients seen by a hematologist at yearly intervals. For high-count CLL-type MBL, CLL-related risk factors including CD38 and CD49D expression, CLL fluorescence in situ hybridization (FISH) markers, and immunoglobulin heavy chain variable region (IGHV) mutation should be evaluated. Cyclin D1 overexpression or t(11;14) should be examined in atypical CLL type MBL. Conventional karyotyping should be considered in both atypical CLL type MBL and non-CLL type MBL. In addition to standard labs, immunoglobulin titers should be followed in all MBL patients, and live vaccinations should be avoided.[3]

Infectious Causes

The most common infections causing lymphocytosis are Epstein-Barr virus (EBV) and cytomegalovirus (CMV). In young children, EBV infection frequently presents as an upper respiratory infection, but in adolescents and young adults, it can result in acute glandular fever with pharyngitis, splenomegaly, lymphadenitis, and profound reactive lymphocytosis. Lymphocytosis is less prominent in older adults. Although the B cells are targeted by EBV, the lymphocytosis consists of CD8$^+$ lymphocytes reacting to neoantigens expressed on the surface of infected B cells. The massive T-cell response usually clears the infection in a matter of days to 1 week, and the lymphocytosis resolves. CMV infection can produce a similar lymphocytosis. However, in the case of CMV, the macrophages are the target of infection, and the T-cell lymphocytosis results from a response to the macrophage neoantigen. CMV infection and lymphocytosis are more common in older adults. In both viral infections, lymphocytosis can be profound, with 50% or more of the circulating white blood cells (WBCs) identified as lymphocytes. Examination of the peripheral smear reveals that up to 10% of the circulating lymphocytes are atypical and larger than normal lymphocytes with open chromatin and increased cytoplasm. It is particularly important to recognize lymphocytosis caused by these two viruses in pregnant women because congenital infection can cause fetal death and birth defects. In addition to EBV and CMV, primary infection with human immunodeficiency virus (HIV) can cause lymphocytosis and should be suspected in the presence of a viral syndrome in the appropriate clinical circumstance. In children, infection with Coxsackie A and B6 viruses, echovirus, and adenovirus can cause a brief but profound lymphocytosis. Infections with other viruses, including human herpesvirus 6 (HHV-6) and HHV-8 as well as rubella virus, varicella, human T-lymphotropic virus type 1 (HTLV-1), and hepatitis viruses, can cause a lymphocytosis, although much less frequently than CMV and EBV.

Important nonviral infections causing lymphocytosis include *Toxoplasma gondii* and *Bordetella pertussis*. In an immune-competent host, *Toxoplasma* infection is often asymptomatic, but patients can have fever, chills, and lymphadenopathy. Mild lymphocytosis with atypical lymphocytes can be observed. As in the case of EBV and CMV, infections during pregnancy can lead to adverse effects on the fetus. In children and adults, infection with *B. pertussis* can lead to lymphocytosis, with the absolute lymphocyte count frequently greater than 10,000/μL. In more severe cases, lymphocytosis is more pronounced.[4] Unlike viral infections and *Toxoplasma* infection, the lymphocytosis observed in *B. pertussis* infection is caused by increases in all lymphocyte subsets, and it appears that the pertussis toxin blocks migration of the lymphocytes from the bloodstream into lymph nodes.[4] Tuberculosis, rickettsial infection, brucellosis, and shigellosis may also cause lymphocytosis.

Physiologic Stress

Lymphocytosis related to physiologic stress is a poorly studied phenomenon. After strenuous physical exercise, subjects develop lymphocytosis, which returns to preexercise levels within 15 minutes to 1 hour of ceasing the activity. The exercise-induced rise is thought to be attributable to catecholamine and steroid hormones and their effect on expression of cell adhesion molecules and on cardiac output and shear stress.[5] Exposure to catecholamines increases the expression of β_2-adrenergic receptors on lymphocytes influencing cell trafficking. Reports suggest that a number of other physiologic stresses, including surgery, trauma, cardiac conditions, sickle cell crises, abdominal pain, and obstetric emergencies, increase lymphocyte counts. In these cases, all lymphocyte subsets appear to increase, but the increase is most profound for CD4 and CD8 memory T cells. Neutrophil counts also rise in these patients, but in most cases, the lymphocytosis resolves before the peak of the neutrophil count.[6]

Drug Reactions

Drug-induced lymphocytosis can occur as part of a hypersensitivity syndrome. In these cases, the lymphocytosis is usually part of a systemic condition that includes a fever, rash, and lymphadenopathy (drug reaction with eosinophilia and systemic symptoms [DRESS]). Elevation in other WBC counts, including eosinophils and monocytes, is common, and atypical lymphocytes are seen. The period between drug introduction and the syndrome is usually approximately 3 weeks, with the most common implicated drugs being aromatic anticonvulsants and sulfonamides.[7] Some studies differentiate this syndrome from drug-induced cutaneous pseudolymphomas in which collections of nonclonal lymphocytes appear in the skin after longer periods of drug exposure, but there is no peripheral lymphocytosis.

Polyclonal B-Cell Lymphocytosis

A final entity causing lymphocytosis is PPBL. This rare disorder is seen primarily in young to middle-aged women who smoke and results in mild polyclonal lymphocytosis. The lymphocytes are medium sized with abundant cytoplasm and a variable proportion is binucleate. A polyclonal increase in serum immunoglobulin M (IgM) is also observed, and there is an association with the human leukocyte antigen (HLA) antigen D-related 7 (DR7) phenotype. Examination of the B cells reveals that most are CD19$^+$, CD5$^-$, and CD23$^-$, with a normal kappa-to-lambda ratio and a variety of heavy chain rearrangements. Adenopathy, hepatomegaly, or splenomegaly has been observed in some, but not all, patients. Genetic analysis has demonstrated the presence of isochromosome 3q in a proportion of B cells, as well as the presence of multiple B-cell lymphoma immunoglobulin *(BCL2-Ig)* gene rearrangements. Similar gene rearrangements have been identified in family members of PPBL patients, along with increases in serum IgM, suggesting that there may be an underlying genetic defect. In vitro studies have shown that PPBL cells proliferate in a CD40-CD154 culture system and secrete both IgM and IgG (isotype switching). This suggests that PPBL may arise from deregulation of the microenvironment or from a defect in a different B-cell activation pathway resulting in extensive proliferation. Overall, the clinical course of this disorder is benign, and the lymphocytosis is not usually progressive; however, clonal B-cell disorders have been seen in a few patients with the disorder, suggesting that it may represent a preneoplastic state.[8]

Lymphocytopenia

Inherited Disorders

Although there are few inherited causes of lymphocytosis, such is not the case for lymphocytopenia, in which the genetic bases of a number of inherited immunodeficiency disorders have been identified. Chief among these disorders is severe combined immunodeficiency (SCID), which is characterized by the absence of functional T lymphocytes. T lymphocytes, B lymphocytes, and NK cells share progenitors, signaling pathways in development and function, and metabolic pathways; thus B lymphocytes, NK cells, or both are often severely affected in SCID. Moreover, in the absence of functional CD4$^+$ T-helper lymphocytes, B lymphocytes cannot function properly, and hypogammaglobulinemia or agammaglobulinemia is observed. In most cases of SCID, the absence of T lymphocytes leads to an extremely low absolute lymphocyte count. In general, SCID is characterized by complete loss of function of the affected gene, whereas hypomorphic mutations of the same genes lead to quite different phenotypes, including Omenn syndrome and "leaky SCID" in which there is some development of T cells but with limited function and repertoire. Defects in more than 30 genes are known to lead to SCID. Inheritance is primarily X-linked or autosomal recessive, but in a few cases, such as the DiGeorge anomaly and some cases of Hoyeraal-Hreidarsson syndrome (defects in telomerase), inheritance is autosomal dominant. In the past, it was useful to characterize SCID syndromes as $T^-B^+NK^+$, $T^-B^-NK^+$, $T^-B^+NK^-$, or $T^-B^-NK^-$ based on the presence or absence of defects affecting B and/or NK cells. SCID can be classified based on the cellular function which is lacking, including deficiency in cytokine-mediated signaling, defects in V(D)J recombination, absent signaling through the T-cell receptor, defects in antigen presentation, and defects in basic cellular processes; the genetic defects for a number of syndromes are now known. Defects in the interleukin (IL)-7 receptor alpha chain *(IL7RA)*, actin-regulating protein coronin 1A (*CORO1A*), CD3 chain components (*CD3D*, *CD3E*, *CD247*), and CD45 (*PTPRC*) lead to $T^-B^+NK^+$ SCID. $T^-B^+NK^-$ SCID defects include deficiencies in cytokine-mediated signaling (*IL2RG*, *JAK3*). Defects in V(D)J recombination (*RAG1*, *RAG2*) or in nonhomologous end joining for repair of double-strand DNA breaks (*DCLRE1C*, *PRKDC*, *LIG4*, and *NHEJ1* mutations) lead to $T^-B^-NK^+$ SCID. Defects that lead to increased lymphocyte apoptosis (*AK2*, *ADA* gene mutations) lead to $T^-B^-NK^-$ SCID and are often associated with anomalies outside of the immune system. Defects in thymic embryogenesis and calcium flux, as well as a collection of other abnormalities, including defects in telomerase activity, can also lead to SCID and are usually associated with abnormalities of other organ systems.[9]

In addition to SCID, other inherited disorders can also perturb T- and B-cell numbers. Patients with classic Wiskott-Aldrich syndrome, caused by mutations in *WAS* (which encodes a cytoplasmic protein responsible for transducing cell surface signals to the actin cytoskeleton), can present with low T-cell counts early in life and become profoundly lymphopenic over time. Abnormalities in immunoglobulins are also noted in this syndrome, with low levels of IgM and high levels of IgA and IgE.[10] X-linked thrombocytopenia is also due to mutations in *WAS*, although clinical presentation is milder probably due to preservation of partial WAS protein expression. Immunodeficiency affects more than half of all patients with ataxia telangiectasia. Patients with ataxia telangiectasia have homozygous or compound heterozygous mutations in the ataxia-telangiectasia–mutated (*ATM*) gene, which encodes a protein kinase with functions in the cellular response to DNA damage. Lymphopenia, especially of naive CD4 cells, is observed in approximately half of patients with ataxia telangiectasia, with mutations leading to absent expression of ATM kinase activity.[11] Heterozygous germline mutations in *GATA2* lead to a spectrum of clinical syndromes characterized by dendritic cell, monocyte, B cell, and NK lymphoid deficiency (DCML deficiency) with elevated Fms-related tyrosine kinase 3 ligand (Flt3L). Mononuclear cytopenia appears to evolve in diverse clinical groups of *GATA2* mutation, including monoMAC syndrome (monocytopenia, B-cell and NK-cell lymphopenia, mycobacterial, fungal, and viral infections and alveolar proteinosis), Emberger syndrome (lymphedema, deafness, and myelodysplastic syndrome [MDS]), and familial (MDS)/acute myeloid leukemia (AML).[12] *GATA2* mutation appears to cause loss of progenitor cells, clonal hematopoiesis, and elevation of Flt3L, but the molecular mechanisms of marrow failure and transformation to MDS or AML are as yet unclear.

Infections

A variety of viral and nonviral infections can lead to lymphopenia. HIV is the most common virus associated with lymphopenia. The target of HIV is the CD4 receptor, and the virus selectively targets and infects activated expanding CD4 T cells. Large studies in HIV-infected patients have shown that peripheral blood CD4 T-cell counts decrease most rapidly in the year after seroconversion (from approximately 1000/µL before seroconversion to 670/µL at 1 year after infection) and then decline more slowly by approximately 50/µL per year.[13] In a subset of untreated patients, viremia is absent or well controlled, and lymphocytopenia develops very slowly if at all; HLA class I alleles, in particular HLA-B, are overrepresented in this group as are rare variants in genes involved in innate immune sensing, CD4-dependent infectivity, HIV trafficking, and HIV transcription. Lymphopenia is an early and reliable laboratory observation in adult influenza infection and is also detected in infections caused by swine influenza (H1N1) and the highly pathogenic avian influenza (H5N1).[14] Lymphopenia has been reported in patients with severe acute respiratory syndrome (SARS) caused by the SARS-coronavirus. Mild illness due to SARS-CoV-2 infection produces lymphopenia in approximately a third of patients, but early reports from Wuhan, China demonstrate that lymphopenia occurred in more than 80% of critically ill patients. In children, respiratory syncytial virus (RSV) infection is associated with a reduction in lymphocyte count, which is most extreme in the sickest patients; similar effects on lymphocyte counts are seen in measles infections (also a paramyxovirus). In West Nile virus encephalitis, lymphopenia is profound and prolonged, and the initial degree of lymphopenia is predictive of outcome. A variety of other viruses can also cause lymphopenia, including herpes viruses (herpes simplex, HHV-6, HHV-8), parvovirus B19, and Dengue virus. In many viral infections, the degree of lymphopenia is correlated with the severity of the disease.[14]

A variety of nonviral infections causes lymphopenia. Infections with *Ehrlichia* (a tick-borne obligate intracellular gram-negative bacteria), *Salmonella typhi*, and *Leptospira* have all been reported to cause lymphocytopenia during the acute illness. CD4$^+$ T-cell depletion has been described in a subset of HIV-negative patients with tuberculosis and low albumin levels, low body weight, and more extensive disease. Recovery of CD4 count after treatment of tuberculosis suggests that the lymphopenia is caused by the tuberculosis infection.[15] Lymphocytopenia is often observed in sepsis and is thought to occur as a result of cytokine-mediated apoptosis of B cells, CD4 and CD8 T cells, and follicular dendritic cells. In autopsy series, most deaths from sepsis occur during the prolonged hypoimmune state, and the more prolonged the sepsis, the more profound the loss of splenic lymphocytes. In one large retrospective study, severe persistent lymphopenia (defined as an absolute lymphocyte count of less than 600 cells/μL) on the fourth day following a diagnosis of sepsis was predictive of development of secondary infections, as well as short- and long-term survival.[16]

Collagen Vascular Disorders

Autoimmune diseases frequently exhibit decreases in circulating lymphocytes. In systemic lupus erythematosus (SLE), lymphopenia (usually decreases in T cells but occasionally in B cells as well) is not only one of the diagnostic criteria but also a parameter used to assess disease activity. Lymphopenia was observed in more than 60% of patients at diagnosis, with the cumulative incidence over the course of the disease reaching more than 90%. Lymphopenia in SLE seems to be more frequent in patients of African descent, and in one study more than half of patients with lymphopenia demonstrated antilymphocyte antibodies. Antigalectin 8 antibodies have been described in patients with SLE, rheumatoid arthritis, and sepsis. In SLE, these autoantibodies are associated with lymphopenia. Apoptosis may also play a role in lymphopenia in SLE, possibly by upregulation of fas antigen on naive peripheral T cells.[17] CD4 T cells may also be decreased in rheumatoid arthritis, and increasing evidence suggests that deficiencies in DNA repair enzymes such as ATM render rheumatoid arthritis T cells sensitive to apoptosis.[18] Apoptotic loss of naive T cells results in lymphopenia-induced proliferation to preserve T-cell homeostasis; this proliferation is now thought to lead to both premature immune aging and an autoimmune-biased T-cell repertoire. In Sjögren syndrome, a minority of patients has been noted to have deficient CD4 counts, and this has been correlated with the presence of anti-CD4 antibodies. Similarly, low lymphocyte counts have been observed in patients with primary vasculitides, type 1 diabetes, and Crohn disease.[17]

Malignancies

Lymphopenia is found in a variety of systemic illnesses; chief among them are cancers. In hematologic malignancies, including Hodgkin lymphoma, diffuse large B-cell lymphoma, and peripheral T-cell lymphoma, patients with lymphopenia have a worse prognosis. Lymphopenia has also been observed in solid tumors, including breast and colon cancer, and soft tissue sarcomas, in which its presence before treatment predicts decreased overall survival. Which specific lymphocyte subsets are involved and the cause(s) of lymphopenia in these tumor types have not been described.

Systemic Disorders

End-stage renal disease (ESRD) has also been associated with lymphopenia, an observation not thought to be exclusively attributable to an effect of dialysis alone. Naive and central memory CD4 and CD8 T cells are significantly reduced in the blood of ESRD patients, apparently because of increased susceptibility of these cells to apoptosis. Lymphopenia occurs in more than 50% of sarcoidosis patients and is associated with chronic disease. Sarcoidosis patients with severe organ system involvement, including neurologic, cardiac, ocular, and advanced pulmonary disease, have lower lymphocyte counts than patients with less severe manifestations (see E-Slide VM03953). Older studies suggest that burn victims have profound decreases in T-cell counts, which may contribute to the infection risk in these patients. Interestingly, lymphopenia is a characteristic of both protein-energy malnutrition and zinc deficiency. Both of these deficiencies perturb the hypothalamic-pituitary-adrenocorticoid axis and increase glucocorticoid levels, which results in increased apoptosis of B and T cells.[19] Intestinal lymphangiectasia, which may be either congenital or secondary to processes that obstruct lymphatic drainage of the gastrointestinal tract, can cause lymphopenia as a result of loss of lymph fluid into the gut along with lymphocytes.

A rare cause of lymphopenia is idiopathic CD4$^+$ lymphocytopenia (ICL), which is defined as a CD4 count less than 300/μL or less than 20% of the T-cell count on two occasions that is not caused by HIV or HTLV infection, drug therapy, or a known immunodeficiency. Patients usually come to clinical notice when they present with opportunistic infections. CD4 T-cell counts typically remain low, but counts do not continue to drop or do not decrease rapidly after diagnosis. In one large series, only approximately 20% of patients recovered from lymphopenia within 3 years of diagnosis. Opportunistic infections plague these patients, and autoimmune diseases occur both before and after the diagnosis of ICL. In ICL, unlike HIV infection, increased activation and turnover are observed in CD4 but not CD8 T lymphocytes.[20]

Drug Effects

A number of drugs are known to cause lymphopenia. Glucocorticoids inhibit production of a number of cytokines and rapidly deplete circulating T cells by enhancing emigration from the circulation, inducing apoptosis, interfering with growth signaling, and inhibiting release from lymphoid tissues. B cells are less affected acutely by glucocorticoid administration, but prolonged administration may result in decreased IgG levels. In clinical trials for multiple sclerosis, delayed-release dimethyl fumarate resulted in a decrease in mean lymphocyte count of approximately 30% in the first year, but approximately 2% of patients had lymphocyte counts less than 500 cells/μL, which persisted for 6 months or longer. Antimetabolite chemotherapeutic agents such as methotrexate, azathioprine, and 6-mercaptopurine lower lymphocyte as well as neutrophil counts, and alkylating agents such as cyclophosphamide have more profound effects on lymphocytes. Purine nucleoside analogs, including cladribine, fludarabine, pentostatin, nelarabine, clofarabine, and others, inhibit DNA synthesis and repair and cause accumulation of DNA strand breaks. All of these agents are associated with profound lymphopenia, which may persist for several years after completion of treatment. In general, T cells are more affected than B cells. Nelarabine in particular is a prodrug of ara-G and is converted to arabinosylguanine triphosphate (ara-GTP), which accumulates at higher levels in T cells.[21]

Monoclonal and polyclonal antibodies directed against lymphocytes are useful in clinical practice and can induce profound and long-lasting lymphopenia. Antithymocyte globulin and alemtuzumab produce depletion of both T and B cells, whereas the monoclonal antibodies OKT3, daclizumab, and basiliximab produce a more pronounced decrease in T cells. The drugs rituximab and ofatumumab are monoclonal antibodies directed against distinct epitopes on B cells. These drugs deplete peripheral B cells but do not routinely produce lymphopenia.

Finally, radiation exposure commonly results in lymphopenia, which occurs before depression of other cell counts. In fact, lymphopenia can develop within the first 24 hours of exposure if the dose of radiation is great enough. Irradiation of the bone marrow, spleen, lymph nodes, and the tumor can all produce lymphopenia. The spleen and lymph nodes are lymphocyte reservoirs and sites for clonal expansion of lymphocytes to specific antigens. Lymphocytes circulating through the radiation portal receive a dose of radiation with each fraction which can result in lymphopenia, particularly when one considers that the D_{50} (dose required for inactivation of 50% of cells) for lymphocytes is only approximately 2 gray. Some patients never recover their lymphocyte count, and this is thought to be due both to the radiation-related destruction of lymphocytes and lack of a surge in compensatory cytokines IL-7 and IL-15 to produce clonal expansion of lymphocytes, maturation, and formation of memory cells.[22]

QUANTITATIVE DISORDERS OF IMMUNOGLOBULINS

In practice, as there are several methods for determining serum immunoglobulin levels, it is critical that age-adjusted normal reference ranges are provided by the laboratory when evaluating immunoglobulin level results. Children first achieve adult levels of IgM around 2 years of age, IgG by 6 years of age, and IgA during puberty. Hypogammaglobulinemia is defined as an IgG more than two standard deviations less than the normal mean or less than 450 to 500 mg/dL, and agammaglobulinemia is usually defined as an IgG level less than 100 mg/dL. Low levels of IgA, IgG, and IgM are characteristic of most forms of SCID.

Hypogammaglobulinemia

Causes of hypogammaglobulinemia can be divided into primary causes related to genetic deficiencies and secondary causes related to malignancies or their treatment, infections, medications, and protein-losing states that deplete antibody.

Secondary Causes

Before embarking on a search for a primary disorder causing hypogammaglobulinemia, it is important to rule out secondary causes. Malnutrition, malabsorption, and any disease state in which large amounts of protein are lost, such as nephrotic range proteinuria, severe burns, lymphangiectasia, or protein-losing enteropathy, can overwhelm the capacity of the B cells to provide adequate immunoglobulin to maintain normal serum levels. Aside from chemotherapeutic agents, a number of medications can produce hypogammaglobulinemia; these include captopril, antiseizure medications (carbamazepine, phenytoin), gold salts, antimalarials, fenoclofenac, penicillamine, and sulfasalazine, as well as glucocorticoids. Infection with HIV and EBV, and congenital infection with rubella, CMV, and *T. gondii* can produce very low immunoglobulin levels and should be ruled out as appropriate. A host of lymphoid malignancies produce hypogammaglobulinemia, but the defect is most profound in CLL, in which up to 70% of patients are said to possess hypogammaglobulinemia even in the absence of treatment, and several studies suggest that this hypogammaglobulinemia at diagnosis is an independent predictor of poor survival.[23]

Primary Immunodeficiencies

The International Union of Immunological Societies has classified the primary immunodeficiency diseases into nine groups, including one class called *predominantly antibody deficiencies*.[9] These disorders present in both adults and children, although some are very rare. Table 50.2 provides a simple grouping of these antibody disorders.

The first group is characterized by a severe reduction in all serum immunoglobulin isotypes, with absence or profound reduction in B cells. Patients with these disorders, particularly those with a well-defined genetic basis, present with severe bacterial infections, most commonly in the respiratory tract (pneumonia, sinusitis, and otitis media), as well as diarrhea caused by bacteria, parasites, and viruses. The prototypic member of this group is X-linked agammaglobulinemia (XLA) caused by a mutation in the Bruton tyrosine kinase (*Btk*) gene, which produces a block in B-cell maturation. Female carriers of a *Btk* mutation are generally asymptomatic, but most boys with XLA come to clinical attention by the age of 1 year. In addition to low-serum immunoglobulins, a clue to the diagnosis is the absence of lymphoid tissue, including tonsils. Autosomal recessive mutations in the μ heavy chain as well as defects in *λ5*, *Igα*, *Igβ*, and *BLNK* produce a similar phenotype. Phosphatidylinositol 3-kinase deficiency (*PIK3R1*) and heterozygous mutation of the E47 transcription factor deficiency (*TCF3*) can cause severe reduction in all serum immunoglobulin isotypes. In a small percentage of patients, no clear molecular defect can be identified. Also included in this group are thymoma with immunodeficiency (Good syndrome) and myelodysplasia. Good syndrome is a poorly understood disorder that presents primarily in middle-aged adults. Immunodeficiency can precede or follow the diagnosis of thymoma and does not resolve with thymectomy. In addition to infections, patients experience autoimmune phenomena, including myasthenia gravis, immune thrombocytopenia purpura, pure red blood cell aplasia, and pernicious anemia. MDSs can also mimic XLA and generally present with low B cells and pancytopenia with monosomy 7, trisomy 8, or dyskeratosis congenita.[24]

A second group is characterized by severe reduction of at least two serum immunoglobulin isotypes with normal or low numbers of B cells. Most patients in this group can be categorized as having common variable immune deficiency (CVID), a heterogeneous disorder characterized by recurrent infection and failure to make antibody to vaccine antigens. Both males and females are affected, and patients can have autoimmune and gastrointestinal disease as well as lymphoproliferative disorders. Autoimmune disease can precede the hypogammaglobulinemia. Approximately 10% of patients with a CVID phenotype have a family history of immunodeficiency. Homozygous or compound heterozygous mutations in *ICOS* (inducible costimulator), which is expressed on activated T cells and plays a role in activating T-helper cells and providing B-cell help, and *CD19*, a B-cell surface molecule that participates in signaling after antigen binding to the B-cell receptor, have been shown to result in recurrent infections in childhood and hypogammaglobulinemia. Mutations in *TACI* (transmembrane activator and CAML-interactor) and *BAFF-R* (B-cell–activating factor receptor) members of the tumor necrosis factor (TNF) receptor superfamily, which play roles in B-cell survival and antibody production, and *MSH5*, a mismatch repair gene, are thought to predispose to CVID

TABLE 50.2 **Predominant Antibody Deficiencies**

	Disease	Mode of Inheritance/ Genetic Locus	Clinical Features
Severe reduction in all serum immunoglobulin isotypes with absent B cells	Bruton tyrosine kinase deficiency	XL/Xq21.3–22	Severe bacterial infections (especially of the respiratory tract), absent lymphoid tissue
	μ heavy chain deficiency	AR/14q32.3	Severe bacterial infections
	λ5 deficiency	AR/22q11.21	Severe bacterial infections
	Igα deficiency	AR/19q13.2	Severe bacterial infections
	Igβ deficiency	AR/17q23	Severe bacterial infections
	BLNK deficiency	AR/10q23.2	Severe bacterial infections
	PIK3R1	AR/5q13.1	Recurrent bacterial infection
	E47 transcription factor deficiency	AD/19p13.3	Recurrent bacterial deficiencies

Continued

TABLE 50.2 **Predominant Antibody Deficiencies—cont'd**

	Disease	Mode of Inheritance/ Genetic Locus	Clinical Features
Severe reduction in at least two serum immunoglobulin isotypes with low or normal B-cell numbers	Common variable immunodeficiency syndromes	≈10% with family history AR or AD	Recurrent respiratory tract infections leading to chronic sinusitis, hearing loss, bronchiectasis, autoimmune disease, lymphoproliferation, malignancy (especially non-Hodgkin lymphoma and gastric carcinoma)
	TACI alterations	AD and AR/17p11.2	
	BAFFR alterations	AR/22q13	
	CD19 deficiency	AR/16p11.2	Recurrent infections
	CD81 deficiency	AR/11p15.5	Recurrent infections
	CD20 deficiency	AR/11q12.2	Recurrent infections
	CD21 deficiency	AR/1q32.2	Recurrent infections
	TNSF12 deficiency	AD/17p13.1	Recurrent bacterial infections, thrombocytopenia, neutropenia
	NFKB1 deficiency	AD/4q24	Recurrent infections, COPD, immune cytopenias
	NFKB2 deficiency	AD/10q24.32	Recurrent infections
	PIK3CD gain of function	AD/1p36.22	Severe bacterial infections
	PIK3R1 deficiency	AD/5q13.1	Severe bacterial infections
	PTEN deficiency	AD/10q23.31	Lymphoproliferations, autoimmune disease.
	MOGS deficiency	AR/2p13.1	Recurrent bacterial and viral infections, severe neurologic disease
	TRNT1 deficiency	AR/3p26.2	Congenital sideroblastic anemia, deafness, developmental delays
	TTC37 deficiency	AR/5q15	Recurrent bacterial and viral infections, abnormal hair
	IKAROS deficiency	AD/7p12.2	Recurrent infections
	IRF2BP2 deficiency	AD/1q42.3	Recurrent infections, autoimmune disease
	ATP6AP1 deficiency	X-linked	Liver disease, leukopenia, low copper
Severe reduction in serum IgG and IgA with increased IgM and normal B-cell numbers (disorders of immunoglobulin class switching)	AID deficiency	AR/12p13	Recurrent bacterial infections and diarrhea, marked enlargement of lymphoid organs
	UNG deficiency	AR/12q23–q24.1	Recurrent bacterial infections and diarrhea, marked enlargement of lymphoid organs
	INO80	AR/15q15.1	Bacterial infections
	MSH6	AR/2p16.3	Cancer history in patient or family
Isotype or light-chain deficiencies with normal B-cell numbers	Ig heavy-chain deficiency	AR/14q32	Most patients are healthy
	κ-chain deficiency	AR/2p11.2	Most patients are healthy
	Isolated IgG subclass deficiency	Variable/unknown	Most patients are healthy
	IgA deficiency associated with IgG subclass deficiency	Variable/unknown	Most patients are healthy
	Selective IgA deficiency	Variable/unknown	Most patients asymptomatic, but increased prevalence of infections, autoimmune disease, atopy, and celiac disease
	Specific antibody deficiency with normal immunoglobulin level and B-cell number	Variable/unknown	Recurrent sinopulmonary infection, bronchiectasis, diarrhea, autoimmune disease
	Inability to make antibodies to specific antigens		
	Transient hypogammaglobulinemia of infancy IgG and IgA deficiency	Variable/unknown	IgG and IgA deficiency. More likely to be male (60%–80%), mild infections and diarrhea, atopy
	CARD11 gain of function	AD/7p22.2	Large spleen, lymphadenopathy, poor response to vaccines
	Selective IgM deficiency	Unknown	Bacterial infections

λ5, Immunoglobulin lambda-like polypeptide (a surrogate light chain subunit that is part of the pre–B-cell receptor); *AID*, activation-induced cytidine deaminase (thought to be essential for initiation of the DNA cleavage required for class-switch recombination and somatic hypermutation); *ATP6AP1*, ATPase, proton transporting, lysosomal, accessory protein 1 (required for luminal acidification of secretory vesicles); *BAFF-R*, B-cell–activating factor receptor; *BLNK*, B linker (a cytoplasmic linker or adaptor protein that plays a critical role in B-cell development); *CARD11*, caspase recruitment domain-containing protein 11; *COPD*, chronic obstructive pulmonary disease; *Ig*, immunoglobulin; *Igα*, immunoglobulin-associated α (necessary for expression and function of the B-cell antigen receptor); *Igβ*, immunoglobulin-associated β (necessary for expression and function of the B-cell antigen receptor); *IKAROS*, a hematopoietic zinc finger transcription factor; *INO80*, the catalytic ATPase subunit of the INO80 chromatin remodeling complex; *IRF2BP2*, interferon regulatory factor 2-binding protein 2; *MOGS*, Mannosyl-oligosaccharide glucosidase; *MSH6*, member of heterodimer required for mismatch-specific binding; *NFκB*, nuclear factor kappa-B; *PI3K-γ*, protein kinase C family member (critical for regulation of cell survival, proliferation, and apoptosis); *PTEN*, phosphatase and tensin homolog (tumor suppressor that antagonizes the PI3K pathway); *TACI*, transmembrane activator and CAML-interactor; *TNSF12*, tumor necrosis factor ligand superfamily, member 12 (weak inducer of apoptosis); *TRNT1*, tRNA nucleotidyltransferase, *CCA-adding*, 1 (adds the CCA terminus to the 3-prime end of tRNA precursors); *TTC37*, tetratricopetide repeat domain-containing protein 37; *UNG*, uracil *DNA* glycosylase (allows creation of single-stranded breaks essential to class switch recombination and somatic hypermutation).

and IgA deficiency but are not sufficient to independently cause their onset. X-linked lymphoproliferative syndrome caused by mutation in the signaling lymphocyte activation molecular-associated protein SAP (gene, *SH2D1A*) can present atypically or later in life with a CVID phenotype.[25] Single-gene mutations of *TNSF12* (*TWEAK*), *NFKB2*, and *CXCR4* have also been demonstrated to cause low levels of immunoglobulins. Autosomal dominant mutations in *PTEN, NFKB1, IKZF1, and IRF2BP2*, and X-lined mutations in *ATP6AP1* have been shown to result in a CVID phenotype and have been added to Table 50.2. Unlike most primary immune deficiencies for which a single gene defect has been identified, CVID is heterogeneous and no genetic defect has been identified in 90% of CVID patients. Class-switch recombination defects encompass a third group of antibody deficiencies and result in hyper-IgM syndrome characterized by reductions in serum IgG and IgA with normal or elevated IgM. X-linked hyper-IgM syndrome due to mutations in the CD40 ligand (*CD40LG*) gene are no longer included in this category because this disease has defects in cellular immunity that now place it into the category of combined immunodeficiency. Defects in the activation-induced cytidine deaminase gene (*AID*) produce hypogammaglobulinemia with recurrent bacterial infections and diarrhea, as well as enlarged lymphoid organs filled with proliferating B cells. A similar clinical picture is produced by homozygous defects in uracil-DNA glycosylase (*UNG*). AID is thought to deaminate cytosine to uracil, and UNG subsequently deglycosylates and removes the uracil residue, creating an abasic site, which allows for creation of single-stranded DNA breaks. Deficiencies in these enzymes result in defective class switching and somatic hypermutation. Patients with similar phenotypes but without defects in *AID* or *UNG* have been described and include mutations in *INO80*, a member of the chromatin remodeling complex and *MSH6* involved in both the induction and repair of DNA double-strand breaks in switch regions.[26]

Additional groups of antibody deficiencies exist in which overall antibody levels are normal, but there are defects in specific isotypes, light chains, or specific antibodies with normal numbers of B cells; the majority of patients with these deficiencies are healthy. The most common member of these groups is selective IgA deficiency, which occurs in approximately 1 in 500 white individuals. The molecular mechanisms underlying this deficiency are unknown, but there is an association with CVID. Finally, an entity termed *transient hypogammaglobulinemia of infancy* has been described in which the normal decline in immunoglobulins after maternal transfer is prolonged. This entity is poorly understood and usually affects boys, who have mild infections and diarrhea. Recovery usually, but not always, occurs by 3 years of age.[27]

Hypergammaglobulinemia

Hypergammaglobulinemia results from an overproduction of immunoglobulins by plasma cells, either monoclonal and reflective of a plasma cell or lymphoproliferative disorder, or polyclonal and accompanying other disease states. The distinction between polyclonal and monoclonal disorders is made by inspection of the serum protein electrophoretic pattern. Detection of one or several monoclonal bands within a polyclonal background is not unusual, and the literature suggests that small bands frequently disappear and do not become clinically relevant. No data are available to suggest that polyclonal gammopathy drives development of monoclonal gammopathy; however, if a clonal plasmaproliferative disorder is suspected, immunofixation or immunoelectrophoresis should be performed.

Disorders Producing Polyclonal Gammopathy

Polyclonal gammopathy usually reflects one of five major disorders, including liver disease, connective tissue disorders, infections, hematologic disorders, and solid tumors.[28] IL-6 and IL-10 have been implicated in polyclonal gammopathy, as have defects in T cells and chronic antigenic stimulation, but the exact sequence of events leading to polyclonal B-cell activation is not known. In general, treatment is directed at the underlying disease, but there are reports of polyclonal gammopathy leading to symptomatic hyperviscosity. In these cases, plasmapheresis and/or corticosteroids seem to be effective. It should also be noted that polyclonal elevations in serum immunoglobulins can sometimes interfere with the direct Coombs test, possibly via nonspecific antibody binding to red blood cells. The degree of gamma globulin elevation does not seem to be helpful in defining the underlying disease state.

In the largest recent review of polyclonal gammopathy, the majority of patients had liver disease, which covered the spectrum from autoimmune disorders (autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis) to viral hepatitis, and alcoholic liver disease. In fact, elevation of serum gamma globulins is a distinguishing characteristic of autoimmune hepatitis, and the levels usually correlate with activity of disease. The most common etiology for polyclonal gammopathy related to liver disease in the United States is likely infection with HCV, but in any particular clinical setting, the exact distribution likely depends on the population demographic. Other diseases affecting the liver, such as α_1-antitrypsin deficiency and hemochromatosis, are also accompanied by increases in serum immunoglobulins.

Connective tissue diseases, including Sjögren syndrome, SLE, ankylosing spondylitis, and rheumatoid arthritis, are also accompanied by polyclonal gammopathy. In many of these diseases, the degree of gamma globulin elevation may reflect disease activity, although a causative link between the autoimmune phenomena and immunoglobulin levels has not been determined. Several of the periodic fever syndromes, which are sometimes classified with the connective tissue disorders, have elevated immunoglobulin levels as a part of their manifestations. Hyperimmunoglobulinemia D is one such syndrome and is linked to mutations in the mevalonate kinase gene. Patients with this disorder present in the first year of life with febrile attacks, lymphadenopathy, abdominal symptoms, arthritis, and oral and genital ulcers. Most, but not all, patients have elevated levels of polyclonal IgD during and between episodes often accompanied by elevated IgA levels. TNF receptor 1-associated periodic syndrome (TRAPS) results from mutation in the gene (*TNRFRSF1A*) for the TNF receptor 1 and can cause prolonged febrile attacks with abdominal pain, arthralgias, and myalgias. During attacks, polyclonal elevation of immunoglobulins (primarily IgA) is observed.[29]

Infections, usually chronic in nature, are frequently accompanied by polyclonal gammopathy. HIV infection is a common cause, and immunoglobulin levels tend to increase slowly until the diagnosis of acquired immunodeficiency syndrome (AIDS) and then decline over the ensuing 6 to 18 months. Polyclonal gammopathy can be a clue to occult infections such as subacute bacterial endocarditis, tuberculosis, perinephric abscess, Lyme disease, and a variety of parasitic infections.

Malignant B- and T-cell disorders can cause polyclonal hypergammaglobulinemia. These diseases include CLL; large granular lymphocytic leukemia; hairy cell leukemia; and angioimmunoblastic T-cell lymphoma (AITL), a rare disease characterized by rash, widespread lymphadenopathy and extranodal involvement, autoimmune phenomena, and polyclonal gammopathy. Interestingly, despite the elevated levels of immunoglobulins observed in AITL, patients exhibit immunodeficiency and a propensity to develop opportunistic infections. Patients with myeloid disorders can also have polyclonal gammopathies; in one large series, nearly 40% of patients with MDS had hypergammaglobulinemia, and patients with immunologic abnormalities had inferior survival.[30] The incidence of hypergammaglobulinemia is reported to approach 50% in chronic myelomonocytic leukemia (CMML). Hypergammaglobulinemia has been reported in AML both in adults and children, but it appears to be a rare phenomenon. Among solid tumors, ovarian and hepatocellular cancers are most commonly associated with polyclonal gammopathy. There are case reports of cancers, particularly lung and breast tumors, producing and releasing the secretory component (SC) of IgA into the bloodstream with the binding of SC to polyclonal IgA, producing hypergammaglobulinemia of serum sIgA.

A variety of other diseases, including asbestos exposure and several subtypes of hypersensitivity pneumonitis and idiopathic interstitial pneumonia, are associated with polyclonal gammopathy. In general, these disorders represent diffuse activation of B cells. Of note, there are reports of polyclonal gammopathy resulting in symptomatic hyperviscosity and these cases have been treated successfully with corticosteroids or plasmapheresis.

Disorders Producing Monoclonal Gammopathy

The differential diagnosis of monoclonal gammopathy includes monoclonal gammopathy of undetermined significance (MGUS), multiple myeloma, solitary plasmacytoma of bone or extramedullary plasmacytoma, Waldenström macroglobulinemia, lymphoma, CLL, and primary systemic amyloidosis. These individual disorders are described elsewhere in this text; however, there are a few points to be made about the M protein itself and MGUS. These disorders can produce intact immunoglobulins (IgG, IgM, IgD, or IgE), κ-, or λ-light chains alone or in combination with intact immunoglobulins, and rarely heavy chains only. The monoclonal protein is usually detected as a discrete band in the γ or β region in serum or urine protein electrophoresis (M spike) and then characterized and confirmed by immunofixation electrophoresis (IFE). Monoclonal antibodies have been associated with a wide variety of bacterial antigens as well as various other antigens, including thyroglobulin, von Willebrand factor, and lactate dehydrogenase; however, for most M proteins, the antigen is not recognized. A variety of other disorders are also associated with an M protein (Table 50.3), including connective tissue

TABLE 50.3 Diseases Associated With Monoclonal Gammopathy

Plasma cell and related disorders	MGUS	See Chapters 89–92
	Solitary plasmacytoma:	
	Bone	
	Soft tissue	
	Multiple myeloma	
	Waldenström macroglobulinemia	
	Primary amyloidosis	
Lymphoid disorders	Non-Hodgkin lymphoma	Monoclonal protein observed in CLL (>20% of cases with IgM, ≈50% with IgG, light chains also observed), extranodal marginal zone lymphomas (>30% of cases and correlated with BM involvement), follicular, mantle cell, and diffuse large B-cell lymphomas also reported with serum M proteins as has AITL
	Hodgkin lymphoma	Rare but reported
	Castleman disease	<2% with monoclonal gammopathy
Other hematologic disorders	Acquired von Willebrand disease	IVIG more effective than factor concentrate in increasing factor VIII coagulant and VWF levels
	Gaucher disease	Observed in 25% in one study; M protein declined after splenectomy
	Pernicious anemia, pure RBC aplasia, hereditary spherocytosis, MPD, MDS	
Connective tissue disorders	SLE	IgG, IgM, and IgA have been observed, no difference in disease activity or outcome
	Inclusion body myositis	80% with IgG M protein
	Polymyositis, RA, scleroderma	
Neurologic disorders	POEMS syndrome	Most have M-protein of λ light chain
	Peripheral neuropathy	Most common is IgM followed by IgG and IgA
		In half, IgM protein binds to myelin-associated glycoprotein
		Size of M protein not correlated with severity of neuropathy
		Some benefit from plasma exchange for those with IgG and IgA
		Fludarabine and rituximab with some benefit for IgM
	Myasthenia gravis, ALS, Alzheimer disease	
Dermatologic disorders	Schnitzler syndrome	Neutrophilic urticarial dermatitis, monoclonal IgM protein, and two of: lymphadenopathy, fever, hepatosplenomegaly, joint pain, increased ESR, increased neutrophils, or abnormal bone imaging
	Scleroderma	
	Pyoderma gangrenosum	Frequently an IgA protein
Infections	HIV	Both IgG and IgM M proteins observed
	HCV	M protein present in up to 10% of patients
Immunosuppression	Renal transplant	In children CMV infection associated with M protein
	Liver and heart transplant	Most patients with posttransplant lymphoproliferative disorders have M proteins
	BM transplant	Observed in both autologous and allogeneic transplants
		Appearance of M protein correlated with GVHD

AITL, Angioimmunoblastic T-cell lymphoma; *ALS*, amyotrophic lateral sclerosis; *BM*, bone marrow; *CLL*, chronic lymphocytic leukemia; *CMV*, cytomegalovirus; *ESR*, erythrocyte sedimentation rate; *GVHD*, graft-versus-host disease; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *Ig*, immunoglobulin; *IVIG*, intravenous immunoglobulin; *MGUS*, monoclonal gammopathy of uncertain significance; *MDS*, myelodysplastic syndrome; *MPD*, myeloproliferative disorder; *POEMS*, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; *RA*, rheumatoid arthritis; *RBC*, red blood cell; *SLE*, systemic lupus erythematosus; *VWF*, von Willebrand factor.

disorders, neurologic disorders (including POEMS [polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes] syndrome), renal disorders, and some infections such as HCV and HIV. Patients undergoing bone marrow and solid-organ transplants in which there is immune suppression are also occasionally observed to have M proteins, but these are usually transient and disappear with recovery of the immune system. Acquired immune disorders such as acquired C1 inhibitor deficiency, type 2 acquired angioedema, and acquired von Willebrand syndrome have also been associated with M proteins.

CHAPTER 51

DISORDERS OF PHAGOCYTE FUNCTION

Mary C. Dinauer and Thomas D. Coates

Phagocytic leukocytes are an essential component of the innate immune system that has evolved to rapidly respond to the presence of invading bacteria, fungi, and parasites. This first line of host defense also includes natural killer (NK) lymphocytes, complement, and other plasma proteins. As reviewed in Chapters 28 and 49, phagocytes are responsible for ingesting, killing, and digesting pathogens. Granulocytic phagocytes (neutrophils and eosinophils) circulate in the bloodstream until they sense chemotactic signals from infected tissues, resulting in adhesion to the vascular endothelium and subsequent migration into the site of infection.[1] In contrast, mononuclear phagocytes (macrophages and their circulating precursor, the monocyte) function primarily as resident cells in a variety of tissues such as the lungs, liver, peritoneal cavity, and spleen, where they perform a surveillance role and also interact closely with lymphocytes to promote specific immune responses. Microbial killing is accomplished by two types of mechanisms: (1) de novo synthesis of highly toxic and often unstable derivatives of molecular oxygen by an enzyme known as *respiratory burst oxidase* and (2) preformed polypeptide "antibiotics" and proteases stored within several types of lysosomal granules that are delivered into phagocytic vacuoles containing the ingested microbes.

This chapter reviews the major congenital and acquired disorders of phagocyte function, which from the clinical standpoint largely involve neutrophils. As would be predicted, these disorders manifest clinically by recurrent bacterial and fungal infections, often with atypical pathogens or unusual presentations. Interestingly, the converse of this is only rarely observed. Most patients with recurrent infections do not have any identifiable abnormality in their phagocytes. There are at least two explanations for the clinical rarity of phagocyte disorders. First, given their critical role in host defense, nature may be quite intolerant of major abnormalities in phagocytes. Before the modern antibiotic era, patients with severe disorders probably did not survive into their childbearing years. Second, there is a remarkable redundancy in the antimicrobial machinery of the phagocytes that permits one system to compensate for a defect in another. For example, the host does not rely on a single chemotactic signal or neutrophil membrane receptor to ensure that phagocytes accumulate at sites of infection. Instead, multiple chemotactic signals and receptors are used. A similar phenomenon is seen in the reactions that kill microbes, as both oxidative and nonoxidative systems are used. It is also important to note that phagocytic leukocytes synthesize and secrete multiple inflammatory mediators, including leukotrienes, chemokines, and other cytokines that amplify and regulate the inflammatory response and initiate cross-talk with adaptive immune cells. Disorders resulting from functional phagocyte defects thus can display not only recurrent, severe bacterial and fungal infections but also aberrant inflammation that is not always related to infection.

This chapter is organized according to the aforementioned cellular functions: disorders of the respiratory burst microbicidal pathway, abnormalities of phagocyte adhesion and chemotaxis, and defects in the structure and function of lysosomal granules. This chapter is not meant to be an encyclopedic review of the numerous papers published on phagocyte abnormalities. It is important to note that many of these reports describe marginal in vitro defects, with little evidence that they are responsible for a clinical problem. Comprehensive reviews offering additional information on phagocyte disorders are available.[2,3]

APPROACH TO DIAGNOSIS OF PHAGOCYTE FUNCTION DISORDERS

Inherited and acquired clinical disorders of phagocyte function result from defects in one or more of the major steps leading to microbial killing—adhesion, chemotaxis, ingestion, degranulation, and production of microbicidal oxidants (Fig. 51.1). Patients with inherited disorders typically present in infancy or childhood with recurrent, unusual, or recalcitrant bacterial and fungal infections, and it is usually not difficult to determine that these are outside the range of normal. The presentation of these different inherited disorders can overlap, so that a specific diagnosis cannot be made on clinical grounds alone. Infections commonly seen include those of skin or mucosa, lung, lymph node, deep tissue abscesses, or childhood periodontitis. These can often have an indolent presentation with only low-grade fevers. Bacterial sepsis is an unusual initial symptom and usually reflects dissemination from an infected site. Inherited defects in phagocyte function are rare and represent only approximately 20% of the primary immunodeficiencies.[2] Thus children with suspected disorders of host defense should also be screened for defects in humoral, cellular, and complement-mediated immunity (see Chapters 23, 50 and 52). An approach to evaluating the patient with significant recurrent infections is shown in Fig. 51.2. Patients in whom a defect is identified should be referred to a center specialized in care of such patients.

In clinical practice, although nearly all patients with well-characterized phagocyte abnormalities have recurrent or unusual infections, the majority of individuals with histories of persistent or recurrent infections do not have identifiable phagocyte disorders or other immune defects. In some cases, these reflect another underlying medical condition or nonimmunologic problem related to an anatomic or obstructive defect. This chapter focuses largely on disorders in which a good correlation exists between the clinical condition and an identifiable defect in phagocyte function.

DISORDERS OF THE RESPIRATORY BURST PATHWAY

Reactive oxygen species generated by the phagocyte respiratory burst are critical for microbial killing. The enzyme responsible for the initial reaction in this pathway is nicotinamide adenine dinucleotide phosphate (NADPH) oxidase found in plasma and phagolysosomal membranes. Upon activation by inflammatory stimuli, NADPH oxidase catalyzes the transfer of an electron from NADPH to molecular oxygen, thereby forming superoxide (as the O_2^- ion; Fig. 51.3, reaction 1).[3–5] This NADPH oxidase, along with enzymes and reactions that are directly involved in the production or metabolism of O_2^-, constitutes the respiratory burst pathway as depicted in Fig. 51.3. Superoxide is the precursor to numerous microbicidal oxidants, including hydrogen peroxide and hypochlorous acid. Five clinically significant defects have been identified in the respiratory burst, involving the following enzymes: NADPH oxidase (reaction 1), leukocyte glucose-6-phosphate dehydrogenase (G6PD; reaction 8), myeloperoxidase (MPO; reaction 4), glutathione reductase, and glutathione synthetase (reaction 9). These reactions are involved in the production of O_2^- (reactions 8 and 1) in the conversion of O_2^- and hydrogen peroxide to other toxic derivatives (reaction 4) or in

Figure 51.1 STEPS IN THE RESPONSE OF CIRCULATION NEUTROPHILS TO INFECTION. The adhesion molecule E-selectin is upregulated on endothelial cells in response to inflammatory mediators (interleukin-1 *[IL-1]*, endotoxin, tumor necrosis factor-α), resulting in rolling attachment and margination through interaction with sialyl-Lewis carbohydrates on its surface. Chemoattractants such as IL-8 cause upregulation of neutrophil β2 integrins that, in turn, mediate tight adhesion to ICAM-1 and PECAM-1 on endothelial cells. Activated neutrophils can detect as little as a 2% change in the chemoattractant gradient and move to the site of infection. Neutrophils phagocytize bacteria opsonized by antibody and complement. Both oxidative and nonoxidative antimicrobial mechanisms are then used to kill bacteria. Disorders of phagocyte function associated with each of these steps are noted. *G6PD*, Glucose-6-phosphate dehydrogenase; *ICAM-1*, intercellular adhesion molecule 1; *NADPH*, nicotinamide adenine dinucleotide phosphate; *PECAM-1*, platelet endothelial cell adhesion molecule 1. *(Courtesy Kyoto W, Coates TD. the detoxification of excess hydrogen peroxide needed to protect the phagocyte during the respiratory burst (reactions 7 and 9). Of note, NADPH oxidase (NOX) homologs to the leukocyte NADPH oxidase are present in the gut, vascular cells, and other tissues, which may generate oxidants for local host defense or for regulation of other cellular functions.[6]

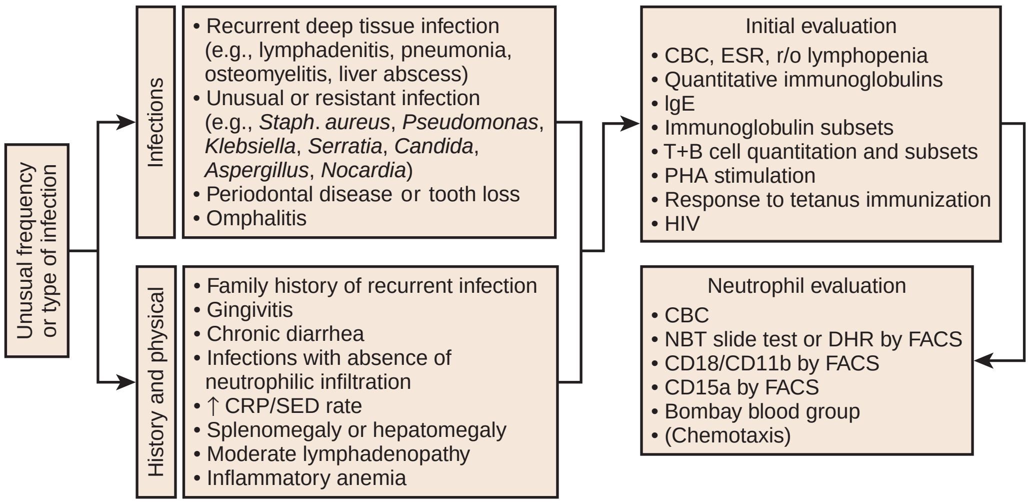
Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is a genetically heterogeneous group of defects that share in common the failure of neutrophils, monocytes, macrophages, dendritic cells, and eosinophils to undergo a respiratory burst and generate O_2^- due to genetic deficiency of the NADPH oxidase.[3,7] CGD is relatively rare, having an estimated incidence of between 1 in 200,000 and 1 in 250,000 live births based on data from the United States CGD Registry,[7] although it is still the most common inherited phagocyte disorder of clinical significance (MPO deficiency is more common, but affected patients are rarely symptomatic). The absence of respiratory burst–derived oxidants results in recurrent, often life-threatening bacterial and fungal infections and is also associated with formation of inflammatory granulomas and other manifestations of aberrant inflammation.[3,7–10] Dysregulated inflammatory responses, which are not always related to infection, reflect a broad impact of NADPH oxidase–derived reactive oxygen species on cellular pathways involved in innate and adaptive immunity.

CGD was first described in 1957 as a syndrome characterized by severe recurrent infections in boys who also had visceral granulomas containing pigmented histiocytes. The disease was termed *fatal granulomatous disease* owing to this distinguishing histologic feature and the grim clinical course in most patients. It was not until the late 1960s and early 1970s that the defect in oxygen consumption and O_2^- production was identified and a convenient diagnostic assay, the nitroblue tetrazolium (NBT) test, was developed. In the 1980s a combination of biochemical and molecular genetic approaches led to the identification of four critical subunits of NADPH oxidase and the recognition that mutations in the corresponding genes are responsible for four different genetic subgroups of CGD (Fig. 51.4).



Unusual frequency or type of infection
Infections
• Recurrent deep tissue infection (e.g., lymphadenitis, pneumonia, osteomyelitis, liver abscess)
• Unusual or resistant infection (e.g., *Staph. aureus*, *Pseudomonas*, *Klebsiella*, *Serratia*, *Candida*, *Aspergillus*, *Nocardia*)
• Periodontal disease or tooth loss
• Omphalitis
History and physical
• Family history of recurrent infection
• Gingivitis
• Chronic diarrhea
• Infections with absence of neutrophilic infiltration
• ↑ CRP/SED rate
• Splenomegaly or hepatomegaly
• Moderate lymphadenopathy
• Inflammatory anemia

• CD18/CD11b by FACS
• CD15a by FACS
• Bombay blood group
• (Chemotaxis)

Figure 51.2 EVALUATION OF PATIENTS WITH RECURRENT BACTERIAL OR FUNGAL INFECTIONS. The history, physical examination, and infections episodes in patients with a possible primary neutrophil dysfunction syndrome are noted. The initial evaluation can be done in most clinical laboratories. A qualified reference laboratory with special expertise in this area should carry out the neutrophil evaluations. Chemotaxis is very difficult to evaluate clinically and should be attempted only in a qualified research laboratory with extensive experience. *CBC*, Complete blood count; *CRP*, C-reactive protein; *DHR*, dihydrorhodamine; *ESR*, erythrocyte sedimentation rate; *FACS*, fluorescence-activated cell sorting; *HIV*, human immunodeficiency virus; *IgE*, immunoglobulin E; *NBT*, nitroblue tetrazolium; *PHA*, phytohemagglutinin; *r/o*, rule out; *SED*, sedimentation.

CLINICAL APPROACH TO PATIENTS WITH DISORDERS OF PHAGOCYTE FUNCTION

Index of Suspicion

Patients with disorders of phagocyte function usually present at a young age with recurrent, deep-seated bacterial and fungal infections. Unlike patients with severe neutropenia caused by bone marrow (BM) failure, these patients usually do not have sepsis. Blood cultures are often negative. The major diagnostic problem faced by the clinician is to determine if the history of infection is unusual enough to warrant consideration of an underlying neutrophil dysfunction defect. The first point to remember is that primary immunodeficiency disorders are rare and primary neutrophil dysfunction syndromes form only a small percentage of all primary immunodeficiency syndromes. The patient is more likely to have recurrent community-acquired *Staphylococcus* infection than chronic granulomatous disease (CGD).

Specific features that may suggest a phagocytic defect are shown in Fig. 51.2. Excellent discussions of this problem have been published (see Kyono and Coates[2] and Dinauer, Newburger and Borregaard[3]). Four aspects of each patient's infection history should be considered: frequency, severity, location, and responsible pathogen. Patients with unusual features in at least one of these aspects should alert the clinician to a possible underlying phagocyte disorder. When considering frequency, the patient's age and associated medical conditions must be taken into account. For example, recurrent otitis media in a 2-year-old patient is far less worrisome than a similar history in a 40-year-old patient. The more unusual or severe the infections, the less frequently these have to occur before a phagocyte evaluation is indicated. Infections in unexpected anatomic locations, such as hepatic, pulmonary, and rectal abscesses, may indicate an underlying phagocyte defect. Childhood periodontal disease or gingivitis is normally very uncommon, and in the absence of neutropenic conditions, strongly suggests underlying neutrophil dysfunction. The identification of certain pathogens (e.g., *Serratia marcescens*, *Klebsiella* spp., *Aspergillus* spp., *Nocardia* spp., *Burkholderia cepacia*, invasive candidiasis) in children and young adults can provide the strongest indications for pursuing further studies. A history of delayed separation of the umbilical cord is often mentioned as a sign of phagocytic defect. This is fairly common as an isolated finding and is usually of no significance. However, this in conjunction with omphalitis or other pyogenic infections raises the possibility of leukocyte adhesion deficiency (LAD) or chemotactic defects. A child with nystagmus, fair skin, and recurrent staphylococcal infections should be evaluated for Chédiak-Higashi syndrome (CHS). Finally, the family history may provide clues suggesting an inherited disorder.

Evaluation

Performing a good history and physical examination to eliminate common causes of recurrent infection is important before looking for rare syndromes. For example, is the recurrent pneumonia caused by an aspirated foreign body in the bronchus? In general, patients should first be evaluated for lymphocyte or complement defects. A useful algorithm is presented in Fig. 51.2. Note that testing described in this algorithm is not exhaustive, and patients with truly striking histories of unusual kinds of infections should be referred for unbiased whole-exome sequencing and further evaluation by specialized research laboratories.

Recently, a fifth genetic subgroup due to mutations in a specialized NADPH oxidase subunit was identified, first in a single patient and subsequently in additional families.[11] Another new and uncommon form of CGD results from defects in a protein important for assembling the NADPH oxidase flavocytochrome.[9] Databases for the main four genetic subgroups of CGD have been developed that are accessible through the websites http://structure.bmc.lu.se/idbase/and http://www.hgmd.cf.ac.uk/ac/index.php. Recent publications on disease manifestations and genotypes in large patient registries are also available and support earlier reports.[3,7,8,10,12,13] Interestingly, common hypomorphic variants in NADPH oxidase genes are linked to autoimmune disorders, particularly systemic lupus erythematosus.[9]

Molecular Genetics of Chronic Granulomatous Disease

CGD results from mutations in any of the five genes encoding subunits of the NADPH oxidase or a gene encoding a chaperone protein (see Fig. 51.4; Table 51.1).[3,9,12,13] These genes are expressed primarily in myeloid cells and in B and perhaps T lymphocytes, although here its function is not well understood. The biochemical and genetic analysis of CGD has been instrumental in characterizing this complex enzyme. The oxidase subunits are referred to by their apparent molecular mass (kDa) and have been given the designation *phox*, for *ph*agocyte *ox*idase. A b-type cytochrome known as flavocytochrome b_{558}, a membrane-bound heterodimer composed of gp91^{phox} and p22^{phox}, is the redox center of the oxidase. In North American, Latin American, and European registries, approximately two-thirds of CGD cases result from defects in the X-linked gene encoding the gp91^{phox} subunit, which contains both the flavoprotein and heme-binding domains responsible for electron transport. X-linked recessive CGD accounts for a smaller percentage of CGD in areas with higher rates of consanguinity, where autosomal recessive (AR) forms are more frequent. One AR form of CGD is caused by mutations in the gene encoding p22^{phox}, the smaller subunit of flavocytochrome b_{558}, which provides a critical docking site for a regulatory subunit, p47^{phox}. Defects in EROS, an endoplasmic reticulum protein that facilitates flavocytochrome assembly, are found in a rare new subgroup of AR CGD. Other cases of AR CGD involve genetic defects in p47^{phox}, p67^{phox}, or p40^{phox}, three regulatory proteins associated with each other in the cytosol of unstimulated cells but which rapidly move to the membrane to activate flavocytochrome b_{558} and superoxide formation upon cell activation by inflammatory or phagocytic stimuli. The p40^{phox} subunit plays a selective role in stimulating high-level superoxide production within phagosomes or endosomes via membrane-bound phosphatidylinositol-3-phosphate. Formation of the active NADPH oxidase complex also involves the activation of the small guanosine triphosphate (GTP)-binding protein Rac, which then binds to the plasma membrane and p67^{phox}.[3] No cases of CGD have been identified resulting from genetic defects in Rac, although a mutation in the blood cell–specific Rac2 isoform was found in an infant with recurrent infections and abnormal neutrophil adhesion, motility, and partial NADPH oxidase defects.[3]

The gene for gp91^{phox}, termed *CYBB*, spans approximately 30 kb in the Xp21.1 region of the X chromosome. More than 600 distinct mutations have been identified in the gp91^{phox} gene in X-linked CGD (MIM306400), which include deletions, frameshifts, splice site, nonsense, and missense mutations that are distributed throughout the gene (Table 51.2).[12] Approximately 10% to 15% of cases of X-linked CGD are caused by new germline mutations. In most X-linked CGD, gp91*phox* is completely absent, and there is no measurable flavocytochrome *b* or superoxide production (the X91° subtype). In about 5% of X-linked cases, gp91*phox* can be present in normal levels but be nonfunctional (X91^{+}), mutated in such a way that gp91*phox* is poorly functional (X91^{-}), or expressed in only a small fraction of phagocytes (X91^{-}). The first two "variant" forms of X-linked CGD result from coding sequence mutations, and the latter are caused by mutations in the regulatory portion of the gp91*phox* gene. Some X-linked CGD patients have large deletions that affect not only *CYBB* but also portions of or all the flanking gene loci for McLeod hemolytic anemia syndrome (absence of the Kell erythrocyte antigen, Kx), Duchenne

DIAGNOSIS OF CHRONIC GRANULOMATOUS DISEASE

The diagnosis of chronic granulomatous disease (CGD) is easily established by doing a nitroblue tetrazolium (NBT) slide test or flow cytometry of dihydroxyrhodamine (DHR) 123 fluorescence to detect neutrophil nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity. The NBT slide test is very easy to set up, as is DHR flow cytometry. However, because the probability of getting an abnormal result is very low, there may be confusion in interpretation because of a lack of experience. In the authors' experience, incorrect positive and negative results have been reported for both assays. Thus, if the index of suspicion is high, consultation should be obtained from a center with extensive experience with the test and with the disorder.

Neutrophil respiratory burst activity is preserved in anticoagulated blood maintained at room temperature for several days; thus DHR testing can be done 1–2 days later after shipping to a commercial laboratory. A normal blood sample should always be shipped with the patient specimen as a control for problems in specimen handling during transport. NBT tests are best performed on the same day the blood sample is obtained.

Nitroblue Tetrazolium Slide Test

- No NBT reduction (absence of cells with dark blue formazan deposits) in both X-linked and autosomal recessive (AR) forms of CGD (see Fig. 51.5B).
- Usually no reduction in 50% of cells and normal in 50% for X-linked carrier. The percent positive cells can vary if there is unequal X inactivation and may appear normal or like CGD with extreme lyonization (see Fig. 51.5C).
- False-positive results can occur (i.e., apparent failure to reduce NBT supporting the diagnosis of CGD) if the neutrophils do not adhere to the slide. This happens with greasy slides or with some cases of leukocyte adhesion deficiency (LAD). Using phorbol myristate acetate to stimulate the cells will avoid this.

Dihydroxyrhodamine Flow Cytometry

- This approach has replaced the NBT slide test in many laboratories. It has the advantage of assessing large numbers of cells and can give quantitation of the amount of oxidant production.
- The change in fluorescence channel number with stimulation is the critical number and not the percent positive cells.
- X-linked CGD patients will not respond at all and show no increase in fluorescence with stimulation (see Fig. 51.5F).
- X-linked carriers will show approximately 50% of the cells that respond with a normal increase in fluorescence, and the other half will have no response. Degrees of unequal X inactivation are much more accurately quantified by this assay (see Fig. 51.5G).
- AR patients, particularly those with absent p47^{phox}, have some response to stimulation and show a small increase in fluorescence (see Fig. 51.5H). This level of oxidant production is usually not visible on the NBT test.
- AR carriers have a good response, but the histogram may be broader than normal and may even appear bimodal with a weakly fluorescent peak and a strongly fluorescent peak. This is not distinguishable on the NBT slide test.
- Falsely negative results not supporting the diagnosis of CGD have been reported in specimens that have been run a few days after phlebotomy.
- Falsely abnormal results suggesting CGD can be seen in patients with myeloperoxidase (MPO) deficiency because MPO is required to generate strong DHR fluorescence.

Genetic Analysis

- Genetic analysis for X-linked and AR CGD is clinically available and should be performed on at least the proband in each kindred.

Those with fewer than 5% oxidase-positive cells have full-blown CGD.

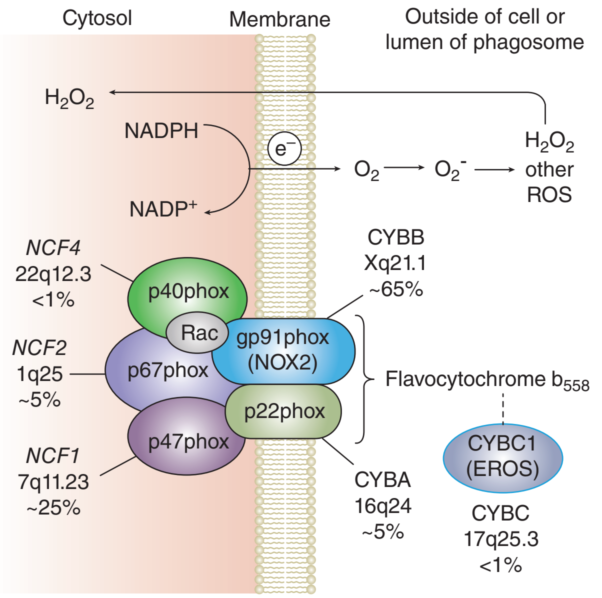

Figure 51.4 NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADPH) OXIDASE AND MOLECULAR GENETICS OF CHRONIC GRANULOMATOUS DISEASE. The leukocyte NADPH oxidase enzyme complex is composed of membrane and cytosolic subunits, referred to by their molecular mass (kDa) and the designation "*phox,*" for ***ph***agocyte ***ox***idase. Chronic granulomatous disease (CGD) results from inactivating recessive mutations in any one of the five *phox* subunits or *CYBC1*, as indicated with the approximate incidence, gene, and chromosomal location. *CYBB* and *CYBA* refer to cytochrome b-245 β chain and cytochrome b-245 α chain, the large and small subunits of flavocytochrome b_{558}, whereas *NCF* refers to neutrophil cytosolic factor, used to designate the cytosolic regulatory subunits of the oxidase. Flavocytochrome b_{558} is the electron transferase and is located in plasma, specific granule (in neutrophils), and phagosome and some endosome membranes. This heterodimer is composed of gp91^{phox} and p22^{phox}, which are affected in X-linked and an autosomal recessive (AR) form of CGD, respectively. The gp91^{phox} subunit, which contains the flavine adenine dinucleotide (FAD) and heme redox centers, is sometimes referred to as NOX2 (**N**ADPH **ox**idase 2). CYBC1, also known as EROS (essential for reactive oxygen species), is an endoplasmic reticulum protein important for expression of the flavocytochrome b_{558} heterodimer and is affected in a rare AR form of CGD. Mutations in the genes encoding p47^{phox}, p67^{phox}, and p40^{phox} account for other AR subgroups. These soluble regulatory proteins form a complex in the cytosol, and upon leukocyte activation, phosphorylation-induced conformational changes lead to their binding to flavocytochrome b_{558} and, for p40^{phox}, to phosphatidylinositol 3-phosphate on phagosome and endosome membranes. The small GTPase, Rac, is also essential for NADPH oxidase enzymatic activity, which in its active GTP-bound state, becomes membrane-bound and activates p67^{phox}. Mutations in Rac do not result in a CGD phenotype. Together, these regulatory proteins activate flavocytochrome b_{558}-mediated transfer of electrons from cytosolic NADPH across the membrane to molecular oxygen, thereby forming superoxide in the extracellular space or within phagosomes or endosomes. Superoxide is converted into H_2O_2, which can diffuse across membranes, and other reactive oxygen species (ROS). *(Originally published in Blood. Dinauer MC. Inflammatory consequences of inherited disorders affecting neutrophil function. Blood. 2019;133(20):2130–2139. © the American Society of Hematology.)*

muscular dystrophy, and X-linked retinitis pigmentosa. Rare missense point mutations in *CYBB* lead to markedly impaired flavocytochrome b expression and activity in macrophages, with much less effects in neutrophils.[14] Affected patients were susceptible to mycobacterial infections but did not have other bacterial and fungal infections characteristic of CGD, highlighting the importance of macrophages for controlling mycobacteria.

AR CGD involving p22^{phox} (MIM 233690) occurs in approximately 5% of CGD patients and usually involves the complete absence of cytochrome *b* (A22°), encoded by *CYBA*. Mutations in A22 CGD are heterogeneous and range from large interstitial gene deletions to point mutations associated with missense, frameshift, or RNA splicing defects.[13] Because the full expression of flavocytochrome *b* in the membrane requires the production of both subunits, a primary deficiency of either component leads to a secondary loss of the other. Thus neither subunit can be detected on immunoblot analysis in either X91° or A22° CGD. A patient with A22$^+$ CGD has been described with a missense mutation disrupting the binding site for p47^{phox}.

AR patients with p47^{phox}-deficient CGD (MIM 233700) account for approximately one-fourth of cases in the United States and Europe, but only approximately 7% of cases in Japan. The p47^{phox} subunit is encoded by the *NCF1* gene. A limited number of mutations have been identified in *NCF1*.[13] Virtually all patients are either homozygotes or compound heterozygotes for a mutant allele with a GT deletion at the beginning of exon 2 that predicts a premature stop codon following the amino acid residue and results in absence of the p47^{phox} protein. The high frequency of the p47^{phox} GT deletion mutation appears to reflect the existence of at least one closely linked highly conserved p47^{phox} pseudogene(s) that contains this GT deletion. This close physical proximity leads to recombination events between the wild-type gene and pseudogene(s).

A heterogeneous group of mutations in the p67^{phox} gene, *NCF2*, are responsible for A67 CGD, a rare AR form of CGD (MIM233710) accounting for approximately 5% of cases overall.[13] Almost all mutations identified to date in A67 CGD lead to absent expression of the p67^{phox} protein. However, one A67$^+$ patient has been reported in which a nonfunctional form of p67^{phox} with an amino acid deletion is expressed but is unable to translocate to the membrane or bind to Rac.

Two additional forms of AR CGD, both with partial loss of oxidase activity, have been described. Affected patients have a different phenotype than "classic" CGD, with more inflammatory manifestations, including granulomatous gastrointestinal disease and lupus-like skin lesions and few if any severe deep-seated infections. Following an initial report in a boy with mutations in *NCF4*, which encodes p40^{phox}, other patients with defects in *NCF4* (MIM613960) were identified in another dozen families.[11] Although NADPH oxidase activity on the plasma membrane is typically normal in p40^{phox}-deficient CGD, intracellular oxidant production is markedly impaired. Another uncommon form of AR CGD results from AR mutations in *CYBC1* (MIM 618935), which encodes the endoplasmic reticulum-resident protein EROS (essential for reactive oxygen species [ROS]) that helps mediate assembly of the flavocytochrome b_{558} heterodimer.[9] Most patients were from Iceland and homozygous for the same founder mutation. *CYBC1* defects seem to affect flavocytochrome b_{558} expression in monocytes and macrophages much more substantially than in neutrophils. Although several patients with *CYBC1* defects developed mycobacterial disease, invasive bacterial and opportunistic fungal infections have not been reported.

Even though more than 90% of patients with CGD have respiratory burst defects that result in undetectable levels of O_2^- production, there is a surprising heterogeneity in the clinical manifestations of the disease.[7] At one end of the spectrum are patients who begin to have severe bacterial and fungal infections during infancy and who rarely have more than 4 to 12 months between such serious infections. At the other end of the spectrum are patients who are well for many years and then unexpectedly develop a serious infection typical of CGD, such as a staphylococcal hepatic abscess or *Aspergillus* pneumonia. After their first major infection, some of these patients may be relatively healthy again for another 3 to 10 years before the next severe infection occurs. As a group, patients with X-linked CGD, A22 CGD, and A67 CGD seem to have a more severe clinical course compared with patients with A47 CGD,[7,8] who have a small amount of detectable oxidant production even in the complete absence of this subunit (Fig. 51.5G). Individuals with partial respiratory burst activity but

[a] In this nomenclature, the first letter represents the mode of inheritance (X-linked *[X]* or autosomal recessive *[A]*), and the number indicates the *phox* component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (°), diminished (–), or normal (+) as measured by immunoblot analysis.

less than 10% of normal (most X91^{-} patients; see Table 51.1) also tend to have disease of intermediate severity. Polymorphisms in oxygen-independent antimicrobial systems or other components regulating the innate immune response are also likely to play an important role in modifying disease severity.[8] Specific polymorphisms in the MPO, mannose-binding lectin, and FcγRIIa genes are associated with a higher risk for granulomatous or autoimmune or rheumatologic complications.[3,9] Finally, as already mentioned, in contrast to "classic" CGD, the clinical spectrum of disease in patients with mutations involving p40^{phox} or *CYBC1* resemble an atypical form of CGD, with inflammatory manifestations much more prominent than infections.[9,11] Because of this heterogeneity, the diagnosis of CGD should be entertained, not only in young children with recurrent severe infections but also in adolescents and young adults who experience exceptionally severe or unusual infections or granulomatous intestinal inflammation.

Clinical Manifestations

In approximately two-thirds of patients, the first symptoms of CGD appear during the first year of life, with the onset of recurrent, purulent bacterial, and fungal infections.[7] Table 51.3 summarizes the types of infections and infecting organisms most frequently encountered in CGD. The most common types of infections are those that involve sites in contact with the outside world, which is consistent with the role of neutrophils as a first line of defense against infection. *Staphylococcus aureus*, enteric gram-negatives, *Serratia marcescens*, *Burkholderia cepacia*, *Nocardia* spp., and *Aspergillus* spp. represent the most frequently encountered pathogens in North American patients, but *Burkholderia* and *Nocardia* spp. are less frequently seen in Europe. *S. aureus* is the most frequently isolated organism overall. CGD patients have increased risk from *Mycobacterium tuberculosis* in endemic areas and can develop severe local or systemic disease with Bacille Calmette Guérin (BCG), an attenuated strain of *Mycobacterium bovis*, following BCG vaccination. The most common causes of death have been pneumonia or sepsis caused by *B. cepacia* and *Aspergillus* spp., although use of newer azole antifungals has markedly improved the outcome of the latter in recent years.[3,7,10]

Most CGD pathogens share the property of being catalase negative, and as such inadvertently "lend" H_2O_2 secreted from the pathogen to the peroxide-starved CGD phagocyte, which in turn uses it (after being converted to hypochlorous acid [HOCl] by MPO; see Fig. 51.3) to kill the microbe. It also appears that at least some of the CGD pathogens are resistant to the nonoxidative killing mechanisms of the phagocyte. It is somewhat surprising how often one fails to identify the infecting organism in CGD—perhaps greater than half the time despite aggressive culturing. In this situation, one treats empirically with the antibiotic that should work and if it fails, one then aggressively pursues more invasive diagnostic procedures looking for one (or more) of the less commonly seen microbes such as *Nocardia* spp., *Candida* spp., mycobacteria, and a host of other bacteria and fungi (see Table 51.3). Other unusual organisms that cause infection in CGD include other members of the *Burkholderia* family, including *Burkholderia*

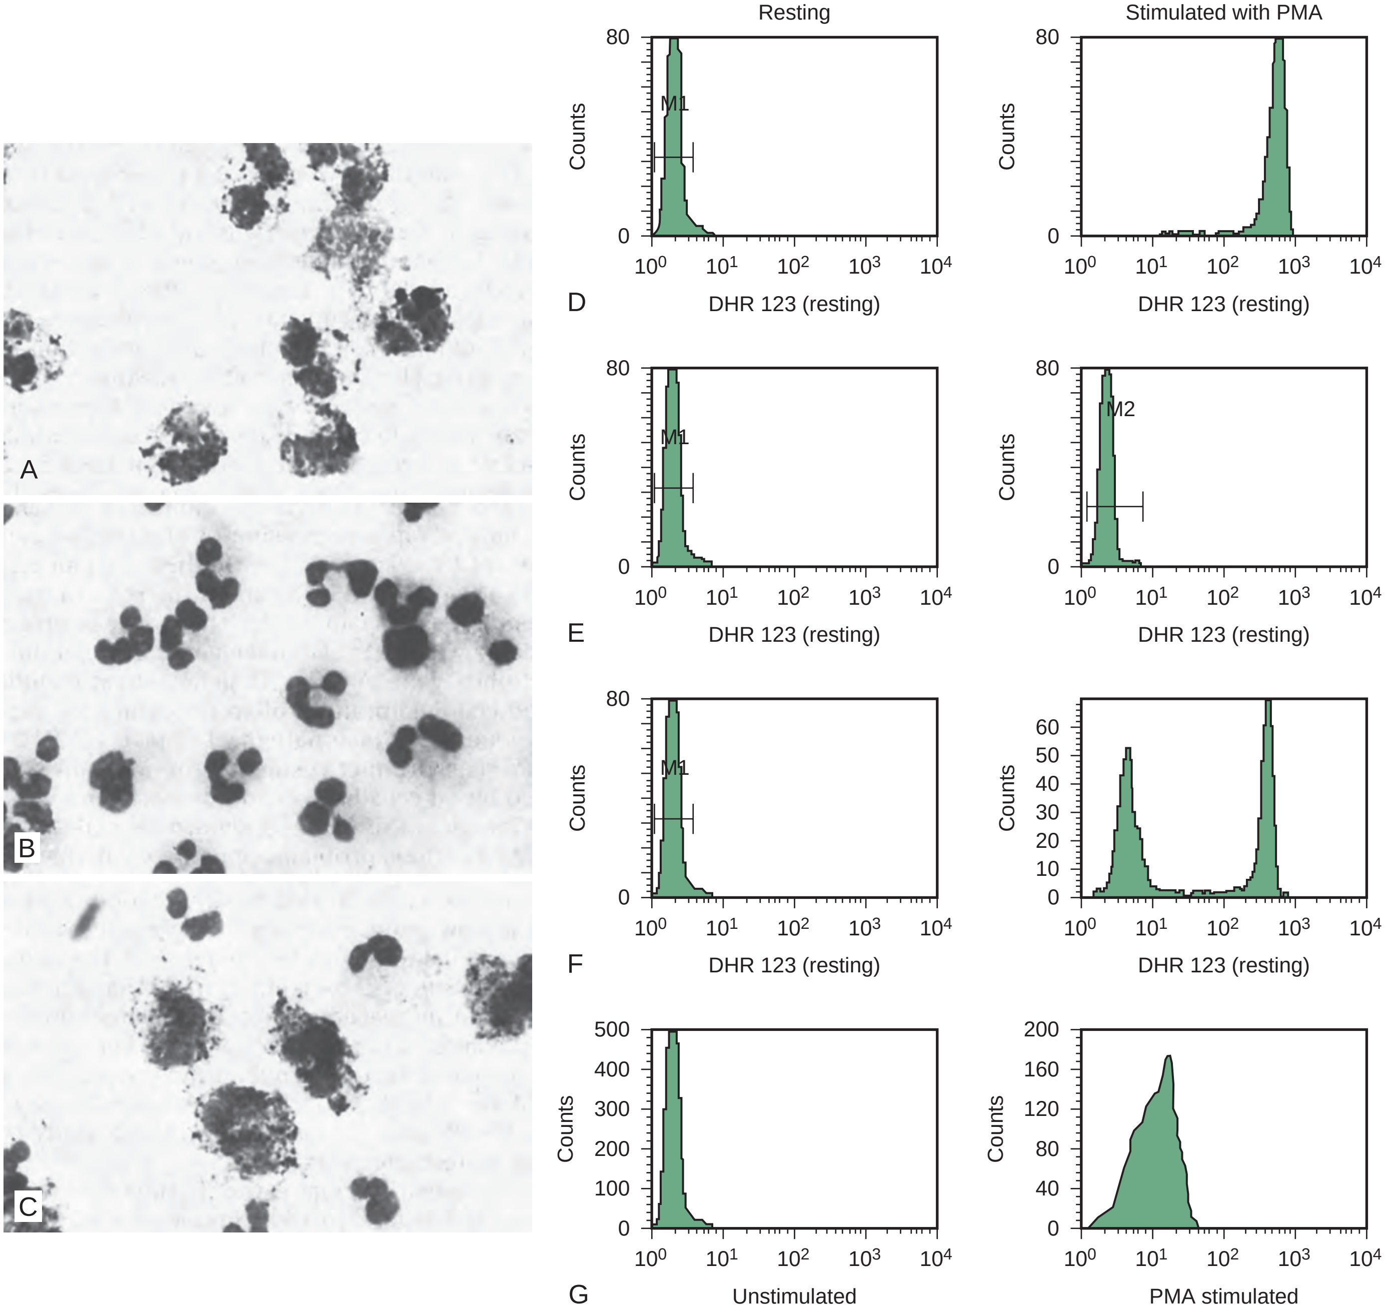

Figure 51.5 ANALYSIS OF NEUTROPHIL NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE OXIDASE ACTIVITY FOR THE DIAGNOSIS OF CHRONIC GRANULOMATOUS DISEASE. (A–C) Nitroblue tetrazolium (NBT) slide test. Peripheral blood neutrophils and monocytes from a drop of fresh whole blood were made adherent to glass slides and stimulated with phorbol myristate acetate. (A) Normal neutrophils and monocytes, all of which are NBT-positive. (B) Neutrophils and monocytes from an X-linked chronic granulomatous disease (CGD) patient, which are all NBT-negative. (C) A mixture of NBT-positive and NBT-negative neutrophils from the X-linked carrier mother of the patient in (B). (D–G) DHR 123 flow cytometry test. Nonfluorescent DHR 123 is taken up by neutrophils, which become fluorescent after reaction with reactive oxygen species produced in the respiratory burst. (D) Normal neutrophils. (E) Neutrophils from an X-linked CGD patient, which do not fluoresce after stimulation. (F) A mixture of nonfluorescent and fluorescent neutrophils from an X-linked CGD carrier. (G) Neutrophils from a p47^{phox}-deficient patient, which show weak fluorescence after stimulation. *DHR*, Dihydrorhodamine; *PMA*, phorbol myristate acetate.

cenocepacia, *Burkholderia gladioli*, and *Burkholderia mallei* (the causative agent in melioidosis, a septic illness common in East Asia), and *Chromobacterium violaceum*, found in brackish fresh water and which can cause a febrile illness with bacteremia in CGD. A previously unknown gram-negative bacteria, *Granulobacter bethesdensis*, was identified in a CGD patient with recurrent fevers associated with chronic necrotizing deep lymphatic infection. This organism is a member of the *Acetobacteraceae* family, which has previously not been linked to invasive human disease.

Pneumonia is the most common type of infection seen in CGD with *S. aureus*, *Aspergillus* spp., *B. cepacia*, and enteric gram-negative organisms as the major pathogens. It is noteworthy that *B. cepacia* has emerged as a particularly lethal organism in CGD. This organism often is not covered with the first line of antibiotics used for *S. aureus* and most gram-negative organisms and can quietly proliferate (with persistent fevers) to the point of quick, explosive collapse caused by endotoxic shock. Intravenous trimethoprim-sulfamethoxazole (TMP-SMX) has been most effective in treating patients if given

TABLE 51.3 Infections in Chronic Granulomatous Disease

Infections	Infections (%)	Infecting Organisms
Pneumonia	70–80	*Aspergillus*, *Staphylococcus*, *Burkholderia cepacia*, *Pseudomonas*, *Nocardia*, *Mycobacterium* (including atypical), *Serratia*, *Candida*, *Klebsiella*, *Paecilomyces*
Lymphadenitis	50–60	*Staphylococcus*, *Serratia*, *Klebsiella*, *B. cepacia, Candida*, *Nocardia, Mycobacteria*
Cutaneous infections/impetigo	50–60	
Hepatic or perihepatic abscesses	20–30	*Staphylococcus*, *Serratia*, *Streptococcus viridans*, *Nocardia*, *Aspergillus*
Osteomyelitis	20–30	*Serratia*, *Aspergillus*, *Paecilomyces*, *Staphylococcus*, *B. cepacia*, *Pseudomonas*, *Nocardia*
Perirectal abscesses or fistulae	15–30	Enteric gram-negative organisms, *Staphylococcus*
Septicemia	10–20	*B. cepacia*, *Pseudomonas*, *Salmonella*, *Staphylococcus*, *Serratia*, *Klebsiella*
Urinary tract infections or pyelonephritis	5–15	Enteric gram-negative organisms
Brain abscesses	<5	*Aspergillus*, *Staphylococcus*
Meningitis	<5	*Candida lusitaniae*, *Haemophilus influenzae*, *B. cepacia*

The relative frequencies of different types of infections in chronic granulomatous disease are estimated from data pooled from mainly several large series of patients in the United States, Europe, and Japan: (1) Mouy R, Fischer A, Vilmer E, et al. Incidence, severity, and prevention of infections in chronic granulomatous disease. *J Pediatr.* 1989;114:555; (2) Bemiller LS, Roberts DH, Starko KM, et al. Safety and effectiveness of long-term interferon gamma therapy in patients with chronic granulomatous disease. *Blood Cells Mol Dis.* 1995;21:239.; (3) Forrest CB, Forehand JR, Axtell RA, et al. Clinical features and current management of chronic granulomatous disease. *Hematol Oncol Clin North Am.* 1988;2:253; (4) Hitzig WH, Seger RA. Chronic granulomatous disease, a heterogeneous syndrome. *Hum Genet.* 1983;64:207; (5) Tauber AI, Borregaard N, Simons E, et al. Chronic granulomatous disease: a syndrome of phagocyte oxidase deficiencies. *Medicine (Baltimore).* 1986;62:286; (6) Cohen MS, Isturiz RE, Malech HL, et al. Fungal infection in chronic granulomatous disease. The importance of the phagocyte in defense against fungi. *Am J Med.* 1981;71:59; (7) Hayakawa H, Kobayashi N, Yata J. Chronic granulomatous disease in Japan: a summary of the clinical features of 84 registered patients. *Acta Paediatr Jpn.* 1985;27:501; and (8) Johnston RB, Newman SL. Chronic granulomatous disease. *Pediatr Clin North Am.* 1977;24:365. These series encompass approximately 550 patients with chronic granulomatous disease (CGD) after accounting for overlap between reports. Unpublished data from the United States CGD Registry encompassing 368 patients was also used to estimate the relative frequencies of infections and the responsible organisms. The infecting organisms are arranged in approximate order of frequency for each type of infection. Note: *B. cepacia* was previously classified as *Pseudomonas cepacia*.

before widespread dissemination of the infection. Proven or suspected *Aspergillus* infections were previously treated with amphotericin B therapy, but azole antifungal agents are now typically used.

Lymphadenitis is the second most common infection and is usually caused by gram-negative organisms, *S. aureus*, or *S. marcescens*. Incision and drainage should not be delayed if the lesion fails to respond to parenteral antibiotics. Cutaneous abscesses should be similarly managed. Recurrent perinatal impetigo is almost a signature infection in CGD and often requires months of therapy (mostly oral antibiotics) to clear. Hepatic (and perihepatic) abscesses are also common in CGD and are usually, but not always, caused by *S. aureus*. Lesions often require drainage (needle or surgical) to permit efficient healing to occur. Bone infections, most commonly caused by *Serratia* spp. or *Aspergillus* spp., are particularly problematic in CGD and arise from either hematogenous or contiguous spread (as often is the case with *Aspergillus* infections in the lung invading the ribs, vertebral bodies, or the diaphragm). Perirectal abscesses are difficult to treat, even with months of therapy, and can lead to fistula formations.

Chronic inflammation with granuloma formation is a distinctive hallmark of CGD and contributes to some of its more problematic complications.[3,9,10] In some cases, this results from imperfectly controlled infections in which stalemates develop between the pathogen and the patient's leukocytes. These lesions become granulomas as the host uses lymphocytes and activated macrophages to assist in containing the pathogens. However, this complication is not always clearly linked to persistent infection and, in these cases, is speculated to involve a dysregulated inflammatory response. Inflammatory complications in CGD are thought to reflect the importance of oxidants generated from the NADPH oxidase to downregulate the inflammatory response through redox-mediated effects, promote efficient degradation of debris, or both. In the absence of oxidant production, excessive production of cytokines and delayed neutrophil apoptosis and clearance at inflammatory sites appear to contribute as underlying mechanisms. Subtle defects in the absence of NADPH oxidase in memory B or T cells may also play a role.

As a result of persistent inflammatory stimulation, CGD patients can have a variety of chronic complications (Table 51.4). Lymphadenopathy, hepatosplenomegaly, eczematoid dermatitis, and anemia of chronic disease (hemoglobin levels usually 8 to 10 g/dL) are common manifestations of this process and are most prominent in the first 5 to 10 years of life in those with CGD. Throughout the body, granuloma formation can lead to dysfunction and obstruction in the esophagus, urinary bladder, and kidneys. In the stomach, the gastric antral narrowing can be severe enough in infants and children to resemble pyloric stenosis. Inflammatory involvement of the gastrointestinal tract can be seen in many CGD patients. A chronic ileocolitis resembling Crohn disease occurs in up to 30% of patients and can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can necessitate a colectomy. Interestingly, antigliadin antibodies suggesting Crohn disease are positive in more than 50% of CGD patients. Inflammatory lung disease with interstitial and/or micronodular infiltrates, often seen better on computed tomography (CT) scan rather than regular X-ray, can develop in many older patients and lead to reduced diffusion capacity and progressive hypoxia. Other types of chronic inflammation include gingivitis, chorioretinitis, destructive white matter lesions in the brain, and glomerulonephritis. Discoid lupus has been reported in 10% to 20% of patients, and occasional patients may develop systemic lupus erythematosus, sarcoidosis, or rheumatoid arthritis. The underlying mechanisms are poorly defined, although recent studies suggest that these manifestations may be partly related to subtle defects in the absence of NADPH oxidase in memory B or T cells. Finally, infections in CGD due to fungi, bacteria (especially *B. cepacia*), or *Leishmania* in endemic areas can trigger the macrophage activation syndrome (MAS) and hemophagocytic lymphohistiocytosis (HLH) in CGD.[9]

Carriers of CGD, whether the X-linked form or any one of the AR forms, are usually asymptomatic, with two important exceptions. First, approximately one-fourth of X-linked carriers are at risk of developing mild to moderately severe discoid lupus erythematosus characterized by discoid skin lesions and photosensitivity.[3,9]

TABLE 51.4 **Chronic Conditions Associated With Chronic Granulomatous Disease**[a]

Condition	Relative Frequency (%)
Lymphadenopathy	98
Hypergammaglobulinemia	60–90
Hepatomegaly	50–90
Splenomegaly	60–80
Anemia of chronic disease	Common
Underweight	70
Chronic diarrhea	20–60
Short stature	50
Gingivitis	50
Dermatitis	35
Hydronephrosis	10–25
Granulomatous ileocolitis	10–15
Gastric antral narrowing	10–15
Ulcerative stomatitis	5–15
Granulomatous cystitis	5–10[b]
Chronic lung disease	10–50[c]
Esophagitis	<10[b]
Granulomatous cystitis	<10
Chorioretinitis	<10
Glomerulonephritis	<10
Discoid lupus erythematosus	<10

[a] The relative frequencies of chronic conditions associated with chronic granulomatous disease (CGD) were estimated from the series of reports listed in Table 50.3.
[b] The incidence is estimated from the 50 cases of CGD followed at Scripps Research Institute and Stanford University (unpublished data).
[c] Chronic lung disease can be especially problematic in adults with CGD; see Campos LC, Di Colo G, Dattani V, et al. Long-term outcomes for adults with chronic granulomatous disease in the United Kingdom. *J Allergy Clin Immunol*. 2021;147:1104 and Dunogué B, Pilmis B, Mahlaoui N, et al. Chronic granulomatous disease in patients reaching adulthood: a nationwide study in France. *Clin Infect Disease*. 2017;64, 767.

The onset is usually in the second decade of life. The disease does not progress to systemic lupus nor does one find serologic evidence of even subclinical disease. Those with severe discoid lupus can be treated with hydroxychloroquine. Recurrent stomatitis, significant gingivitis, or both have also been noted in as many as half of X-CGD carriers. A few also have arthralgias, polyarthritis, and Raynaud phenomenon. The second important complication of the X-linked CGD carrier state is serious infection in women who have an unusually high degree of inactivation of the normal X chromosome in their myeloid cells. If the circulating neutrophil population is skewed to the point that fewer than 10% to 15% of the cells function, then the carrier has an increased risk of bacterial infections that in some cases have been severe.[3]

Diagnosis

The diagnosis of CGD is usually suggested by the unusual clinical histories outlined earlier or by a family history of CGD. The NBT slide test on fresh blood is the classic diagnostic test. A typical result is shown in Fig. 51.5. Fig. 51.5A shows the normal positive staining of a group of seven neutrophils and one monocyte. Fig. 51.5B shows the complete absence of NBT staining in a patient with X91° CGD, the classic X-linked form of the disease. Fig. 51.5C shows the mixed population of NBT-positive and NBT-negative cells observed in that patient's mother, reflecting random X chromosome inactivation. Because nearly 100% of the normal cells in this test are positive, the carrier state in X-linked CGD can be detected when as few as 5% of the cells are NBT-negative. This test also permits detection of diffuse populations of weakly positive cells such as those seen in X91^{-} CGD, which are characterized by a partial deficiency of flavocytochrome *b*. Because X-linked CGD can arise by new mutations in the maternal germline, one does not always see NBT-negative cells in the mother. Flow cytometric assays of oxidase activity, such as those based on the conversion of dihydroxyrhodamine (DHR) 123 to rhodamine 123, can also provide both quantitative measurements of oxidant generation and the cell-by-cell distribution of activity (see Fig. 51.5D–G). The DHR 123 assay for oxidase activity is now available in many referral centers and reference laboratories. In addition to X91^{-} CGD neutrophils, weak staining in the NBT test or a small but measurable level of DHR fluorescence can be seen in A47° cells (see Fig. 51.5H) because of a small amount of residual oxidant production. Regardless of diagnostic assay used, it is important to have these tests performed on appropriately handled blood samples and by experienced laboratories to avoid inconclusive or false-normal results.

Genetic testing is useful to solidify the diagnosis and for genetic counseling and is commercially available for the five genetic subgroups involving NADPH oxidase subunits (see Table 51.1). The analysis of mutations in *NCF1* can require specialized polymerase chain reaction (PCR) testing due to the presence of adjacent pseudogenes. Laboratories specializing in neutrophil biochemistry can also perform immunoblot analysis of neutrophil extracts, flavocytochrome *b* spectroscopy, or functional analysis of membrane and cytosol fractions in the cell-free oxidase assay.

Testing for the McLeod red cell phenotype should be done in patients diagnosed with X-linked CGD who harbor large *CYBB* deletions that potentially involve the locus encoding the Kell erythrocyte antigen. Loss of Kell causes a mild hemolytic anemia. More importantly, there can be serious problems with development of hemolytic antibodies if these patients are transfused with Kell-positive blood.

Prognosis and Treatment

The cornerstones of therapy in CGD are currently (1) prevention and early treatment of infections, (2) aggressive use of parenteral antibiotics for most infections, (3) use of prophylactic TMP-SMX (5 mg/kg/day of trimethoprim) or dicloxacillin (25 to 50 mg/kg/day) for sulfa-allergic patients, (4) prophylactic itraconazole (200 mg/day if 13 years of age or older or if weighing at least 50 kg, or 100 mg daily if younger than 13 years of age or weighing less than 50 kg), and (5) use of prophylactic recombinant human interferon-γ (rIFN-γ; 0.05 mg/m^2 or 0.0015 mg/kg if less than 0.5 m^2 three times per week).[3,15] Using these guidelines, the prognosis for patients with CGD has improved dramatically since the disorder was first described in the 1950s, when almost all patients died in childhood. In a large study based on data collected by a CGD registry in the United States in the 1990s, the overall mortality rate was estimated to be 5% per year for X-CGD and 2% per year for AR CGD,[7] and a more recent single-institutional study of 76 patients reported an overall mortality rate of 1.5% per year.[3]

There is a general consensus that a large majority of newly diagnosed children should survive well into their adult years with aggressive and careful management. While survival is improved, many of these adults continue to have significant complications due to chronic inflammation.[10] The quality of their survival is further affected by the paucity of providers with sufficient experience in the management of this very rare disorder. As already noted, patients with deficiency of p47^{phox} have a tendency for milder disease compared with those with flavocytochrome-negative CGD.[8] On the other hand, some patients (usually X-linked) prove to have more frequent serious infections or inflammatory complications (or both), likely because of the effects of modifier genes; these patients may warrant more aggressive treatment such as bone marrow transplantation (BMT; see later).

Several approaches can be used to prevent infections. Patients with CGD should receive all their routine immunizations on schedule (including live virus vaccines), with influenza vaccine administered each year as well. Cuts and skin abrasions should be cleansed promptly with soap and water and a topical antiseptic applied (2% hydrogen peroxide, Betadine ointment, or both). Frequent brushing, flossing, use of antibacterial mouthwash, and professional cleaning of teeth can help prevent gingivitis. Constipation should be avoided because it can lead to rectal or anal fissures and abscesses. Early anal infections can be treated with soaking in soapy water (with or without betadine). The frequency of pulmonary infections can be reduced by not using commercially available bedside humidifiers; avoiding smoking (cigarettes and marijuana); and refraining from handling decaying plant materials (e.g., hay, mulch, rotting sawdust), which often contain numerous *Aspergillus* spp. Avoidance of construction sites, especially demolition of old buildings that may harbor fungi, is recommended. There have been clear outbreaks of *Aspergillus* pneumonias in immunosuppressed children visiting hospitals undergoing renovation.

There is clear evidence that chronic prophylactic TMP-SMX can decrease the number of bacterial infections in CGD patients by more than half without a concomitant increased risk of fungal infection. In addition, itraconazole is an effective agent for prophylaxis for fungal infections in CGD. Liver function tests should be monitored in patients receiving itraconazole.

Prophylactic rIFN-γ has been another mainstay of current management of CGD.[3] The clinical benefit of rIFN-γ is probably related to generally enhanced phagocyte function and killing by nonoxidative mechanisms because its use is not accompanied by any measurable improvement in NADPH oxidase activity in the vast majority of CGD patients. In the original multicenter trial, patients were randomized in a double-blind fashion to receive either placebo or rIFN-γ ($0.05\,\text{mg/m}^2$ three times per week). As summarized in Table 51.5, there was a substantial decrease in the number of serious infections in the rIFN-γ arm. Side effects were observed in some of the patients but typically were restricted to mild fever and flu-like symptoms. Additional adverse reactions, including any increased incidence of chronic inflammatory complications, have not been noted with more prolonged courses of prophylactic rIFN-γ (more than 10 years), and the patients continued to have a substantial benefit, with fivefold fewer serious infections compared with the placebo group in the phase III study in Table 51.5. This group of patients averaged one serious infection per patient every 4 to 5 years. However, rIFN-γ is used less frequently in Europe because nonrandomized trial data did not suggest much benefit. The use in a cohort followed at the National Institutes of Health was recently reported to be only 36% of patients because of either lack of access or because of side effects (fever, myalgia); the availability of more potent antifungals and oral antibiotics may be a mitigating factor for reducing serious infectious complications in the absence of prophylactic rIFN-γ.

One of the most frequent errors in the management of CGD patients is the failure to treat potentially serious infections promptly and aggressively with appropriate parenteral antibiotics. Even the best antibiotics can be rendered ineffective if given too late in the course of an infection in CGD. Therefore early intervention is advisable. Although many of the minor infections and low-grade fevers in CGD patients can be managed on an outpatient basis, episodes of consistently high fever over a 24-hour period or clearly established infections (e.g., pneumonia or lymphadenitis) should be treated with parenteral antibiotics that cover, at least initially, *S. aureus* and enteric gram-negative organisms. Reasonable attempts to define the source of the infection and the responsible microbe should also begin promptly. The use of PCR to supplement culture-based methods to detect microbial pathogens may be very helpful. A few organisms can cause a large inflammatory response, so often an organism cannot be found and empiric treatment must be administered without specific identification of an organism. Monitoring markers of inflammation such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) can be very useful, both as a clue to the presence of a significant infection as well as following the patient's response to therapy. If the patient fails to respond, then more aggressive diagnostic procedures should be instituted (CT, bone, and gallium scans; open biopsies if indicated) and empirical changes in the antibiotics used to broaden coverage to *Pseudomonas cepacia*. If fungus is identified or strongly suspected, amphotericin B has been the drug of choice in the past, but newer azole antifungal agents such as voriconazole are supplanting its use.

Even with appropriate antibiotics, certain types of infections respond slowly and may require many months of therapy. This point about duration of treatment is critical. Especially deep tissue infections such as pneumonia require continued treatment until they are clear radiographically, and the sedimentation rate has normalized. This can take many months of intensive treatment. Otherwise, the infection will recur and long-term complications such as emphysema develop. In this sense, treatment of infection in CGD is very different than the normal population. Surgical drainage or resection can sometimes play a key role in accelerating healing of certain types of infection such as lymphadenitis, osteomyelitis, and abscesses of visceral organs such as the liver or lung. Corticosteroids in combination with high-dose antibiotics can help to avoid surgical intervention for liver abscesses. Finally, granulocyte transfusions may be of benefit in the treatment of stubborn or life-threatening infections.[3,7,10,15]

Recurrent fever in CGD always raises the possibility of infection in these patients; however, the MAS-HLH spectrum of disorders should be considered, especially if the patient has splenomegaly, leukopenia, or thrombocytopenia. If significant MAS/HLH is suspected, IFN-γ should be stopped. As in inflammatory disorders such as rheumatoid arthritis, secondary MAS-HLH has been reported in CGD, often in association with bacterial or fungal infection, and is probably often overlooked (see Chapter 53). Specific treatment may be indicated,

especially if the patient has significant cytopenias or evidence of hepatic dysfunction.

Inflammatory complications of CGD can occur at all ages but can be an increased burden in adults. These can be challenging to treat in CGD because use of agents to suppress the inflammatory response can increase the risk of fungal or bacterial infections.[3,9,10,15] Judicious use of corticosteroids can be indicated, including in cases of severe asthma, esophageal strictures, gastric antral narrowing, granulomatous cystitis, inflammatory bowel disease, or certain cases of pneumonia. Clear evidence shows that corticosteroids are beneficial in these clinical settings because the steroids induce rapid regression of obstructive symptoms at low oral doses (e.g., 1 mg/kg/day of prednisone). Steroids can be lifesaving in young children with airway obstruction because of inflammation. Because of the exaggerated inflammatory reaction seen in CGD, there can be significant swelling in the airway and compression by pulmonary nodes that can block air movement and impede drainage. In these cases, the physician and patient should be aware of the risks of the additional immunosuppression caused by corticosteroids, particularly for fungal infection. Corticosteroids have also emerged as important component of treating *Staphylococcal* liver abscesses in combination with antibiotics, with improved outcomes and often avoidance of invasive procedures for abscess drainage. In colitis, steroid-sparing agents such as sulfasalazine and azathioprine for colitis can be helpful. Biologic agents such as TNF-α inhibitors or those blocking IL-1 are also occasionally used in patients with difficult-to-manage inflammatory disease, but with caution due to the increased risk of infection. The chronic lung disease that can develop in older patients with CGD can be difficult to treat and may be an indication for stem cell transplantation.

Rare patients with X91° CGD have genomic deletions that span the gp91^{phox} gene and the Xk gene, which encodes a membrane protein necessary for expression of the Kell genes.[3] Absence of the Xk gene product results in the McLeod syndrome, in which red blood cells have weak Kell antigens and variable acanthocytosis along with nerve and muscle disorders related to its expression in nonerythroid tissues. Transfusion of patients with McLeod syndrome poses a serious problem because they can develop alloantibodies of wide specificity that can preclude any further transfusions except with Kell-negative blood products. McLeod-matched blood is extremely rare, and patients with this syndrome should have their own blood frozen in case it is needed. Note that use of maternal blood does not solve the problem because only 50% of the mother's blood will match. Because of the difficulty in finding blood, transfusion with non-McLeod blood is likely to occur. Although management is difficult and use of steroids is necessary, the hemolytic anemia can be managed successfully.

Allogeneic hematopoietic stem cell transplant (HSCT) can be used to treat CGD, including using matched unrelated donors.[10,16] Because of risks associated with this procedure, HSCT was previously considered only for patients who have a fully human leukocyte antigen (HLA)-matched sibling and frequent and severe infections or refractory gastrointestinal disease despite aggressive medical management. However, reduced-intensity conditioning regimens for allogeneic transplantation with sibling or nonsibling donors have now been successfully used for HSCT in CGD and has a high curative rate with low mortality.[10,16] Which patients with CGD should undergo transplantation is an individualized decision, particularly for those with residual NADPH oxidase activity, for adults, or when well-matched donor marrow is not available. The best results are in young patients without preexisting complications. Because it is currently not possible to predict which patients will develop significant inflammatory complications such as gastrointestinal or lung disease later in life, transplantation in the first decade of life should be strongly considered for any patient with a fully HLA-matched healthy sibling or fully matched high-resolution HLA-typed unrelated donor, regardless of infection history. The indications for transplant in adults should be carefully assessed in consultation with an experienced HSCT center, although results in recent years have been encouraging. While the resolution of gastrointestinal disease in CGD following transplant has been appreciated for some time, the problematic inflammatory lung disease with progressive dyspnea that can develop in older CGD patients also appears to be reversible to a remarkable degree with successful HSCT.

Finally, gene therapies aimed at correcting the defective gene in bone marrow (BM) stem cells hold promise for the future if obstacles can be solved to achieve effective and safe gene delivery and their transplantation (see Chapter 104).[10] Observations on female carriers of X-linked CGD with skewed X-inactivation and preclinical studies in murine CGD models suggest that complete correction of NADPH oxidase activity in 10% of circulating neutrophils will lead to clinically relevant improvements in host defense, although inflammatory complications may still be problematic if only partial correction is achieved.

Neutrophil Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH, the primary substrate for the respiratory burst oxidase, is generated by the first two reactions of the hexose monophosphate shunt pathway, which are catalyzed by G6PD (see Fig. 51.3, reaction 8) and 6-phosphogluconate dehydrogenase (6PGD).[17] The leukocyte and erythrocyte G6PD are encoded by the same gene. Thus a severe deficiency of G6PD in neutrophils can result in a greatly attenuated respiratory burst because of low levels of NADPH. However, the vast majority of individuals with inherited G6PD deficiency do not have problems with a decreased respiratory burst or recurrent infections. A CGD-like syndrome has very rarely been observed in G6PD-deficient patients who have congenital nonspherocytic hemolytic anemia (CNSHA), in whom hemolysis occurs in the absence of redox stress.[3,17] Even in CNSHA, most G6PD mutations cause the enzyme to decay over a period of days and weeks, so that levels in the short-lived neutrophil usually do not become critically low even in some of the most unstable G6PD variants (see Chapter 45). A few rare and poorly understood G6PD mutations that cause CNSHA are associated with extremely low (<5% of normal) levels of G6PD in the neutrophil, resulting in a deficient respiratory burst and CGD-like symptoms. The combination of chronic, severe hemolytic anemia, recurrent infections, and the laboratory demonstration of extremely low G6PD levels in neutrophils and erythrocytes serves to distinguish this disease from CGD. The treatment for neutrophil G6PD deficiency is the same as for CGD, except that the efficacy of rIFN-γ has not been demonstrated in the former. The chronic hemolytic anemia is treated by supportive means, including transfusions.

Disorders of Glutathione Metabolism

As depicted in Fig. 51.3 (reaction 6), the reduced form of glutathione (GSH) serves to protect the neutrophil from the harmful effects of hydrogen peroxide on NADPH oxidase and other neutrophil proteins. Adequate intracellular levels of GSH are maintained by recycling oxidized glutathione (GSSG) to GSH by glutathione reductase (see Fig. 51.3, reaction 7), as well as by de novo synthesis of glutathione by glutathione synthetase (see Fig. 51.3, reaction 9). Severe deficiencies in either of these enzymes are extremely rare and are apparently inherited in an AR manner.[3] In the case of glutathione reductase deficiency, the respiratory burst terminates prematurely, presumably owing to the toxic effects of accumulating hydrogen peroxide on NADPH oxidase. However, this brief burst of O_2^- appears to be sufficient for adequate microbial killing because the few patients reported have not had problems with recurrent infections. However, they do have congenital hemolytic anemia during periods of oxidant stress caused by diminished levels of glutathione reductase in erythrocytes. In glutathione synthetase deficiency, the respiratory burst proceeds normally. Patients have severe metabolic acidosis caused by elevated levels of

5-oxoproline, which is the product of the first step in glutathione synthesis and is present in increased levels because of a lack of feedback of GSH on the synthetic pathway. Patients with glutathione synthetase deficiency also have intermittent neutropenia (perhaps caused by the acidosis), as well as oxidant-induced hemolysis. There are mild problems with recurrent infections. Therapy with vitamin E (400 IU/day) has been found to be beneficial in patients with severe glutathione synthetase deficiency with hemolysis and infections.

Myeloperoxidase Deficiency

MPO deficiency is the most common inherited disorder of phagocytes but is almost always asymptomatic.[18] MPO is present in azurophilic granules of neutrophils and monocytes and catalyzes the production of a potent antimicrobial agent, HOCl, from chloride and hydrogen peroxide (see Fig. 51.3, reaction 4).[4,5] HOCl in turn reacts with a variety of primary and secondary amines to form chloramines, some of which can be toxic. Moreover, HOCl is capable of activating latent metalloproteinases (e.g., collagenase) and inactivating antiproteinases.

Complete MPO deficiency is seen in approximately 1 in 4000 individuals, and partial deficiency is even more common (1 in 2000 persons). The key features of MPO deficiency are summarized in Table 51.6. The disorder is inherited in an AR manner. In the few cases reported, several different mutations have been identified, which generally appear to affect the posttranslational processing of a precursor polypeptide for MPO. Acquired forms of MPO deficiency are also seen. The gene that encodes for MPO is located on chromosome 17 at q22–q23 near the breakpoint for the 15-to-17 translocation of promyelocytic leukemia. Subpopulations of MPO-deficient cells can be seen not only in the M3 (promyelocytic) form of acute myeloid leukemia but also in the M2 and M4 forms. MPO-deficient cells are also seen in approximately 25% of patients with chronic myeloid leukemia and myelodysplastic syndromes.

One of the most curious features of MPO deficiency is the remarkable lack of clinical symptoms in affected persons, given the prediction that severe MPO deficiency would cripple important antimicrobial reactions catalyzed by **hypochlorous** acid (HOCl). In vitro an impressive defect in killing *Candida albicans* and hyphal forms of *Aspergillus fumigatus* is observed.[18] Bacterial killing in vitro is also abnormal in being somewhat slower than normal, but eventually it is complete. MPO-deficient mice also exhibit abnormalities in host defense against *Candida* and *Klebsiella* spp. However, excessive or unusual infections in MPO-deficient patients are uncommon, except for rare individuals who also have diabetes mellitus.[18] In these individuals, disseminated fungal infections (usually candidiasis) are seen.

The discrepancy between the in vitro and in vivo manifestations of MPO deficiency in most patients can be explained in several ways. First, the respiratory burst in MPO-deficient neutrophils is substantially augmented, presumably from the absence of HOCl-mediated toxic effects on the NADPH oxidase. Second, other products of the respiratory burst, together with the oxygen-independent antibacterial proteins, appear to have sufficient potency to compensate for the loss of MPO-dependent reactions. Finally, residual amounts of MPO coupled with the normal levels of eosinophil peroxidase may provide at least some degree of peroxidative activity at the sites of infection.

Treatment is usually not required for MPO deficiency except in those individuals with fungal infections. In these patients, aggressive use of antifungal antibiotics is indicated. The prognosis is excellent in the majority of patients with MPO deficiency.

TABLE 51.6 Summary of Myeloperoxidase Deficiency

Incidence	1 in 2000 (partial deficiency) 1 in 4000 (total deficiency)
Inheritance	Autosomal recessive with variable expression; MPO gene on chromosome 17 at q22–q23
Molecular defect	Defective posttranslational processing of an abnormal MPO precursor polypeptide; eosinophil peroxidase encoded by different gene and levels normal
Pathogenesis	Partial or complete MPO deficiency leads to diminished production of HOCl and HOCl-derived chloramines; MPO products are necessary for rapid killing of microbes (especially *Candida* spp.) but not absolutely required
Clinical manifestations	Usually clinically silent Disseminated candidiasis or fungal disease (rare; usually in conjunction with diabetes mellitus) Acquired deficiency in M2, M3, and M4 AMLs and myelodysplasia
Laboratory evaluation	Deficiency of neutrophil and monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal, killing of bacteria in vitro Failure to kill *Candida albicans* and hyphal forms of *Aspergillus fumigatus* in vitro
Differential diagnosis	Acquired partial MPO deficiency seen in M2, M3, and M4 AML; MDS; and Batten disease
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetics
Prognosis	Usually excellent

AML, Acute myeloid leukemia; *HOCl*, hypochlorous acid; *MDSs*, myelodysplastic syndromes; *MPO*, myeloperoxidase.

DISORDERS OF PHAGOCYTE ADHESION AND CHEMOTAXIS

Numerous investigators have found in vitro chemotactic abnormalities in neutrophils from patients with a wide variety of clinical disorders associated with increased susceptibility to bacterial and fungal infections.[3] In most circumstances, the chemotactic abnormality identified was only marginal and not always clearly related to the clinical status of the patient. In other instances, clear and major defects were identified in vitro that correlated with the in vivo propensity for infection. Extensive classification systems have been devised to categorize the numerous acquired defects in chemotaxis. The problem in many of these reports is that it is unclear whether the infections were caused by the in vitro chemotactic abnormality or by the medical complications of the underlying disorder (e.g., acidosis, malnutrition, or exposure to nosocomial infections). A further complicating factor is that there are inherent limitations in the in vitro chemotaxis assay, which is subject to laboratory artifacts both as a result of neutrophil purification procedures as well as the assay itself. Furthermore, the extent to which these in vitro chemotactic assay systems faithfully reflect prevailing in vivo conditions is not known. Our understanding of chemotactic disorders has been hampered by the limitations of these assays, just as the elucidation of respiratory burst defects was obscured when the major available assay was in vitro bacterial killing. In this section, the most important and best characterized of the chemotactic disorders, leukocyte adhesion deficiency (LAD), is discussed in detail. A brief discussion of several other clinically significant chemotactic disorders is also provided.

DIAGNOSIS OF CHEMOTACTIC DISORDERS

The direct measurement of neutrophil chemotaxis in a clinical setting is challenging and requires a specialized research laboratory. Because the assays are biologic assays, the laboratory must run the tests at least monthly to maintain competence and have acceptable normal ranges. Neutrophil chemotaxis is significantly affected by inflammation, complement activation, and medications, making it very difficult, especially in a patient with infection, to determine if the infection is attributable to a chemotactic defect or if the defect is attributable to the infection. This is further complicated by the fact that inflammation activates the neutrophils and affects which populations actually come off of the density gradients required to separate the cells for assay. Unlike the respiratory burst, chemotaxis must be done on fresh cells, so samples cannot be reliably shipped.

The neutrophils from patients with primary chemotactic defects have almost no motility in standard biologic assay systems. Some chemotactic disorders can be diagnosed by assays of other characteristic features.

Leukocyte Adhesion Deficiency I (LAD I)

- LAD I has a significant chemotactic defect as well as phagocytic defect and is characterized by leukocytosis. The diagnosis can be made by flow cytometry of the CD11b complex on the surface.
- Fig. 51.6 indicates surface expression of C3b and CD11b on neutrophils. C3b is used as a positive control and is normal in LAD1. With stimulation, CD11b increases *(top panel)*.
- The results in this assay are expressed as percent of normal stimulated control mean channel number. It is important to note that this is not the percent positive cell, as is the case for most flow cytometry assays.
- Severe LAD1 has no increase with stimulation.
- Moderate LAD1 shows some shift of fluorescence with stimulation.
- Genetic analysis for this disorder is clinically available.

Other chemotactic disorders: Genetic analysis is available for several primary neutrophil defects, and this approach should be pursued before attempting assay of chemotaxis in a clinical setting.

No other primary chemotactic defects are readily diagnosed by a routine clinical laboratory. Measurement of neutrophil chemotaxis itself to look for secondary defects for any kind of clinical decision making is difficult if not impossible to interpret.

TABLE 51.7 **Summary of Leukocyte Adhesion Deficiency Type 1**

Incidence	More than 300 patients described in literature
Inheritance	AR
Molecular defect	An absent, diminished, or structurally abnormal β subunit (CD18) caused by one of several types of mutations in the β gene; in the absence of a normal β subunit, the three types of α chains in the β2 integrin subfamily (CD11a, b, c) cannot assemble into normal α–β heterodimers
Pathogenesis	All three β2 integrins (CD11a/CD18, CD11b/CD18, and CD11c/CD18) are deficient on all leukocytes, causing multiple abnormalities in cell function: adherence; chemotaxis; and C3bi-mediated ingestion, degranulation, and respiratory burst
Clinical manifestation	Persistent granulocytosis (neutrophil count: 12,000–100,000/mm^3) Severe or moderate phenotypes depending on severity of deficiency Recurrent pyogenic infections with absent neutrophil infiltration Delayed umbilical cord separation Severe gingivitis or periodontitis
Laboratory evaluation	Flow cytometric measurement of surface CD11b in stimulated neutrophils with monoclonal anti-CD11b
Differential diagnosis	CGD May be associated with severe neutrophil actin dysfunction
Therapy	Hematopoietic stem cell transplant in clinically severe patients (CD11b <0.3% of normal) Aggressive use of parenteral antibiotics Possible benefit of prophylactic TMP-SMX
Prognosis	Severe: high incidence of death before 2 years of age unless transplantation is performed Moderate: can survive into 20s and 30s but with recurrent infections

AR, Autosomal recessive; *CGD*, chronic granulomatous disease; *TMP-SMX*, trimethoprim–sulfamethoxazole.

Leukocyte Adhesion Deficiency Type I

LAD type I (LAD I) is a rare AR disorder of leukocyte adhesion, chemotaxis, and ingestion of C3bi-opsonized microbes as a result of decreased or absent expression of the leukocyte β_2 integrins (Table 51.7).[19,20] The hallmark of LAD I is the occurrence of repeated, often severe bacterial and fungal infections without the accumulation of pus despite persistent granulocytosis (see Table 51.7). The molecular basis for LAD was first suggested by Crowley and colleagues, who found that neutrophils from a patient with this clinical syndrome lacked a high-molecular-weight membrane glycoprotein (see Dinauer, Newburger, and Borregaard[3]). The patient's neutrophils could not be made to adhere to plastic surfaces or to respond to serum-opsonized particles in terms of ingestion and respiratory burst activity.

The molecular basis of LAD I is now known to result from mutations in the gene for the common CD18 β2 subunit for these three leukocyte glycoproteins, now termed *β2 integrins*, that belong to the integrin superfamily of adhesion molecules (see Chapter 15). Integrins are noncovalently linked heterodimeric glycoproteins consisting of an α and a β subunit. Within each of the eight known integrin subfamilies, the β subunit is identical (and defines the subfamily), but the α subunit varies and confers the functional specificity on the integrin. The molecular defect in LAD involves all members of the β2 integrin subfamily: αL β2 (CD11a/CD18), αm β2 (CD11b/CD18), and α× β2 (CD11c/CD18). CD11a/CD18 is often referred to as *LFA-1*, and CD11b/CD18 is also called *Mac-1*, *Mo1*, or *CR3*. LAD I patients have an absent, diminished, or structurally abnormal β2 subunit (CD18; see later), and as a result, the three types of α chains in the β2 integrin subfamily cannot assemble into normal α–β heterodimers. Thus all three β2 integrins are moderately to severely deficient on all leukocytes in LAD.

The β2 integrins serve as receptors for the opsonic complement fragment C3bi, the intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2) that are expressed on endothelial cells and leukocytes, and fibrinogen. The diminished or absent expression of β2 integrins in LAD I leukocytes results in the failure of phagocytes to emigrate from the bloodstream to sites of infection. The early interactions with the endothelium, termed *rolling*, are normal in LAD I because these are mediated by a different family of adhesion molecules known as *selectins*. However, β2 integrins are responsible for the subsequent tight binding of neutrophils and monocytes to ICAMs on cytokine-activated endothelium, and this step is therefore severely defective in LAD I. Transendothelial migration is also impaired. A second major functional defect in LAD is the failure of phagocytes to bind C3bi-opsonized microbes. Because CD11b/CD18 is the predominant phagocyte receptor for this complement fragment, C3bi-mediated ingestion, degranulation, and respiratory burst activity are severely affected in LAD. Finally, β2 integrin–dependent signals play a key role in activating neutrophils for enhanced migration, phagocytosis of antibody-opsonized microbes, and degranulation.

Despite in vitro defects in lymphocyte responses dependent on LFA-1 (CD11a/CD18), patients with LAD I rarely have clinical manifestations related to impaired lymphocyte function. It is believed that the role CD11a/CD18 plays in lymphoid cell function can be compensated by other adhesion proteins (CD2, CD4, CD8, and so on).

Molecular Genetics of Leukocyte Adhesion Deficiency Type I

The fact that LAD I involves a deficiency of all leukocyte β2 integrins focused attention on the common β2 chain (CD18), and mutations in the corresponding gene, *ITGB2*, have been identified in all LAD I patients who have been analyzed at the molecular level to date.[19,20] Although expression of the leukocyte integrin α subunits is normal in LAD I, these are not transported to the cell surface because the β2 chain is absent or contains mutations that disrupt its structure or its interaction with the α subunit. Mutations in the α subunits have not been found thus far in patients with LAD I. The CD18 glycoprotein has a large extracellular domain at the N terminus, a single transmembrane domain, and a 46-residue cytoplasmic tail. CD18 mutations in LAD I are heterogeneous in nature and family specific and can lead to either undetectable or low (9% to 20% of normal) levels of α–β dimer expression that correlates with the clinical severity of the disease. More than 50 different mutations have now been characterized in more than 100 families.[20] These include missense mutations, messenger RNA (mRNA) splicing defects, small deletions, and a premature termination signal. Many patients are compound heterozygotes and have two different mutant alleles for CD18. About half of patients with LAD I in whom the genetic defect has been identified have point mutations in a stretch of 250 amino acids in the extracellular domain of CD18. This region is highly conserved among all β subunits and appears to be important for interaction with the α subunit.

Clinical Features

The key features of LAD I are summarized in Table 51.7. The clinical presentation of LAD is heterogeneous and is related to the severity of the deficiency of the β2 integrins. The severe clinical phenotype is associated with less than 0.3% of the normal amount of these glycoproteins on the leukocyte surface; the moderate phenotype has 2.5% to 6% of normal levels. In both the severe and moderate forms of the disease, persistent granulocytosis (neutrophil count of 12,000 to 100,000/mm^3) is a constant finding, as are recurrent cutaneous abscesses and aggressive periodontitis and gingivitis. Recent studies suggest that impaired migration and clearance of neutrophils in periodontal tissues results in a dysregulated interleukin (IL)-23 to IL-17 inflammatory axis, which drives the severe periodontal disease typical of LAD I rather than impaired control of gum bacteria.[21] Additional clinical features seen more often in the severe clinical phenotype include delayed umbilical cord separation, omphalitis, perirectal cellulitis, severe ulcerative stomatitis, and bacterial sepsis. A striking finding in LAD I is that abscesses and other sites of infections are devoid of pus despite the marked neutrophilia because neutrophils are unable to emigrate to tissues. *S. aureus* and gram-negative enteric bacteria cause the majority of infections in LAD I. Fungal infections can also occur, particularly from *C. albicans* and *Aspergillus* spp.

Note that infants with delayed separation of the umbilical cord who are healthy and have normal blood counts are very unlikely to have LAD I. Although the mean age of cord separation ranges from 7 to 15 days, 10% of healthy infants can have cord separation at 3 weeks of age or later.

Diagnosis

The diagnosis of LAD I is made by flow cytometric measurement of surface CD11b (Mac1; or the shared CD18 subunit) in unstimulated and stimulated neutrophils using commercially available monoclonal antibodies directed against CD11b or CD18 (Fig. 51.6). Neutrophils contain an intracellular pool of CD11b/CD18 in their secondary (specific) and tertiary granules, which can be mobilized to the cell surface during stimulation. Therefore the deficiency of CD11b can be more dramatically demonstrated by using stimulated neutrophils. Carriers of LAD I can be identified by this method because they have been found to express approximately 50% of normal levels of CD11b on the surface of their stimulated neutrophils (see Fig. 51.6).

Prognosis and Treatment

Treatment of LAD I depends on the clinical severity of the disorder. In patients with the moderate clinical phenotype, cutaneous and oral infections can be managed as they occur. The use of prophylactic antibiotics such as TMP-SMX appears to be beneficial, as does aggressive prophylactic treatment of periodontal disease, which could also potentially benefit from agents targeting the IL-23 axis. It is important to note that even patients with the moderate phenotype can die of overwhelming infection. In patients with severe LAD I, aggressive management is indicated because of the high incidence of death before the age of 2 years, and HSCT is recommended. LAD I should also be amenable to gene-replacement therapy in the future.

Leukocyte Adhesion Deficiency Types II and III

LAD type II is a very rare clinical syndrome closely related to LAD I but caused by a defect in selectin-mediated adhesion events from a deficiency in leukocyte sialyl-Lewis X ligands.[3,19] It was first reported by Etzioni et al. in two unrelated boys of Muslim Arab origin and has since been described in a total of five individuals (four Arab and one Turkish). The disease is inherited in an AR manner. Patients

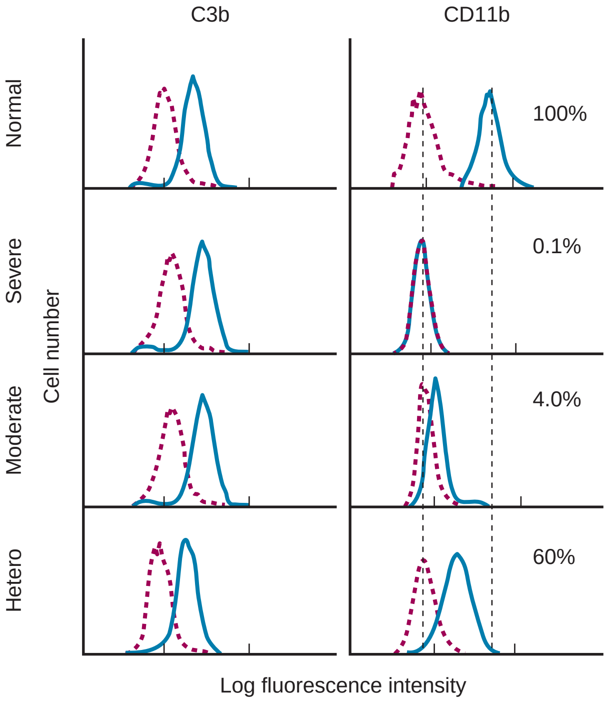

Figure 51.6 EVALUATION OF ADHESION MOLECULE EXPRESSION FOR DIAGNOSIS OF LEUKOCYTE ADHESION DEFICIENCY. Fluorescence of C3b-specific antibody labeled neutrophils *(solid line)* increases compared with a nonspecific control *(dashed line)* after 30-minute exposure to 10-nM N-formylmethione-leucyl-phenylalanine (fMLP) in healthy donors, patients with severe and moderate forms of leukocyte adhesion deficiency (LAD) I, and a heterozygous LAD I carrier. However, the increase in CD11b fluorescence *(solid line)* is markedly diminished in LAD I patients. The respective percent of normal stimulated mean channel number is shown in the *right column*. Note that these results are expressed as percent of normal fluorescence intensity, not as percent of positive cells, as is the case in most flow cytometry assays.

present with neutrophilia, recurrent bacterial infections, and periodontitis, similar to LAD I, although these symptoms were generally not as severe. In addition, LAD II is associated with dysmorphic features and psychomotor retardation. LAD II neutrophils express normal levels of CD18. A clue as to the molecular cause of LAD II came from the observation that LAD II red cells were Lewis antigen–negative and also had the rare Bombay (hh) erythrocyte phenotype, in which red blood cells express a nonfucosylated variant of the H antigen. These antigenic defects share in common the failure to form certain fucose carbohydrate linkages. The defect in fucose metabolism in LAD II has now been shown to result from mutations in the Golgi guanosine diphosphate–fucose membrane transporter. This leads to a generalized loss of expression of fucosylated glycans on the surface of cells, particularly the sialylated and fucosylated tetrasaccharide, SleX (CD15a), on the neutrophil surface. As a result, LAD II neutrophils are unable to bind to E- and P-selectin receptors on endothelium and therefore have an impairment in the early steps of rolling and loose binding to blood vessel walls before tight adhesion and emigration into infected tissues. Fucose supplementation has been partially successful in increasing expression of SLeX and decreasing clinical problems.

LAD type III has been described in a handful of patients with severe, recurrent infections similar to LAD I, as well as a bleeding tendency similar to Glanzmann thrombasthenia (a β3 integrin–related disorder).[3,19] This disorder results from AR defects in KINDLIN-3, a regulatory protein required for "inside-out" activation of multiple classes of integrins in blood cells. Because the clinical manifestations are typically severe, early BMT may be indicated for patients with LAD III (see Etzioni[19]).

Hyperimmunoglobulin E Syndrome

Hyperimmunoglobulin E syndrome (HIES) is a complex disorder characterized by markedly elevated serum immunoglobulin E (IgE) levels, serious recurrent staphylococcal infections, mucocutaneous candidiasis, chronic dermatitis, and skeletal and dental abnormalities.[22] Although not a primary phagocyte defect, neutrophils from patients with this syndrome exhibit a variable and at times profound chemotactic defect. HIES was first described in 1966 and was called *Job syndrome*, in reference to the biblical description of Job as being affected by "sore boils from the soles of his feet unto his crown." The skin abscesses in patients with HIES lack the erythema that is typical of such lesions and are referred to as *cold abscesses*. The key features of HIES are described in Table 51.8. The disorder is rare, affecting fewer than 1 per million population.

Most cases of HIES result from inherited or sporadic autosomal dominant negative (DN) mutations in signal transducer and activator of transcription 3 (STAT3), a Janus kinase (JAK)-activated transcription factor activated in response to many cytokines and growth factors. These mutations, which are usually a result of missense or in-frame deletions and located primarily in regions of the protein that interact with other proteins or with DNA, inhibit the activity of the wild-type STAT3 allele and result in a complex pattern of altered cytokine signaling and impaired T helper type 17 (Th17) cell differentiation. Mutations in *DOCK8*, a guanine nucleotide exchange factor, or *TYK2*, a JAK family member, result in an AR immunodeficiency with some overlap with HIES features but have more profound impairment in lymphocyte functions, leading to a broader risk of infection and other immune dysregulation. DOCK8 deficiency has recently been recategorized from HIES to combined immunodeficiency[22] and will not be further discussed in this chapter (see Chapter 52).

Insights into how STAT3 signaling defects lead to the clinical syndrome characteristic of DN STAT3-HIES are now emerging. Defective responses to IL-6 may account for the minimal inflammatory responses characteristic of HIES, and the enhanced IgE production may reflect dysregulated immune responses secondary to impaired signaling by IL-10, a negative regulator. Th17 cells are important for control of mucocutaneous *Candida* infection, which is problematic in many patients. In addition, keratinocytes and bronchial epithelial cells are particularly dependent on Th17 cytokines to produce chemokines and antimicrobial peptides, which may explain the predilection for skin and lung infections. The dental and skeletal abnormalities may be related to defective STAT3 signaling in osteoblasts and osteoclasts.

MANAGEMENT OF INFECTIONS

The management of infections in patients with primary neutrophil dysfunction syndromes is quite different than in the normal population and for the most part different from other patients with neutropenia.

- Patients tend to present with relatively low fevers and chronic inflammatory processes associated with marked elevation of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Unless they have untreated abscesses or inflammatory masses, they tend not to present with frank sepsis and positive blood cultures.
- The frequency of infections decreases somewhat with age in children as their normal T cell– and B cell–mediated immunity develops.
- Although one should always attempt to obtain culture proof of an infection, more often than not, it is not possible to identify an organism, and it is necessary to treat empirically.
- Because these patients tend to develop deep-seated tissue infections, the ESR can be of great value even though it is quite nonspecific. Elevation in the ESR suggests deep tissue inflammation; CRP is more acute and suggests monocyte activation. Persistent significant elevation of the ESR (>15–20 mm/h) even in the absence of fever or other symptoms may warrant radiologic search for deep-seated infection.
- The authors advocate an "antibiotic sensitivity by ESR response" approach to empiric therapy in stable patients. One can start at parenteral anti-*Staphylococcus* and gram-negative therapy and monitor the ESR daily. A monotonic decrease in the ESR within several days that is clear-cut suggests the process is sensitive to the antibiotic selected. Although complete resolution of inflammatory response may take many weeks, usually there is some clear change in the ESR within 1 week. If there is worsening or no clear response, then an antifungal can be added and the ESR monitored in the same fashion. Return of an elevated ESR can be a sign of development of organism resistance.
- If a patient with chronic granulomatous disease (CGD) is particularly ill appearing or febrile, it is important to make sure that *Burkholderia cepacia* complex bacteria are covered.
- There is no fixed duration of therapy for any infections in these patients, but antibiotic treatment must often be prolonged. The duration of therapy is critical, and if the infections are not completely extinguished, they will return and will contribute to development of chronic pulmonary and hepatic fibrosis. Parenteral antibiotics or antibiotics that can deliver very high tissue levels should be continued significantly past normalization of the ESR and disappearance of any radiographic evidence of deep tissue infection. This can take many months for some pneumonias and liver abscesses.
- Short pulses of steroids (4–6 days) can be lifesaving, particularly for pulmonary infections in young children with CGD. They reduce airway inflammation and promote drainage. Steroids can also be useful for management of liver abscesses in CGD.
- Young children are susceptible to infections with routine childhood viruses and infections and tend to do well with standard therapeutic approaches and courses of treatment that are 2 to 3 times longer than the usual recommended course. Again, monitoring with the ESR can be a guide.

All standard childhood immunizations and influenza vaccinations are strongly recommended. Prophylactic antibiotics may be appropriate (see text).

Clinical Manifestations

The clinical manifestations of STAT3-HIES are at times dramatic. Onset is generally in the first 2 months of life and is manifested

TABLE 51.8 Summary of Signal Transducer and Activator of Transcription 3–Hyperimmunoglobulin E Syndrome

Incidence	More than 300 patients reviewed in the literature
Inheritance	AD with incomplete penetrance; sporadic forms with de novo mutations
Molecular defect	Dominant negative mutations in STAT3 (AD inheritance or de novo mutations)
Clinical manifestations	Staphylococcal pneumonia Pneumatoceles Fungal superinfection of lung cysts "Cold" cutaneous skin abscesses and furuncles Chronic eczematoid dermatitis Mucocutaneous candidiasis Coarse facies, growth retardation Osteopenia, recurrent fractures Sinusitis, keratoconjunctivitis Scoliosis Hyperextensible joints Delayed shedding of primary teeth Vascular disease
Laboratory evaluation	Serum IgE >2500 IU/mL Peripheral blood eosinophilia Immunophenotyping for Th17 cells
Differential diagnosis	Atopic dermatitis Wiskott-Aldrich syndrome, DiGeorge syndrome Hypergammaglobulinemia Chronic granulomatous disease
Therapy	Prophylactic anti-*Staphylococcus aureus* antibiotics Aggressive treatment of acute infections with parenteral antibiotics Surgical drainage of deep infections and resection of lung cysts Monitor for scoliosis, fractures, vascular disease
Prognosis	Generally good if managed aggressively

AD, Autosomal dominant; *HIES*, hyperimmunoglobulin E syndrome; *IgE*, immunoglobulin E; *STAT3*, signal transducer and activator of transcription 3; *Th17*, T helper type 17.

by chronic dermatitis. By 5 years of age, patients have a history of recurrent skin abscesses, pneumonias, chronic otitis media, and sinusitis. As patients grow older, recurrent staphylococcal pneumonia is a common problem and can be complicated by the formation of pneumatoceles that can become colonized with *Pseudomonas aeruginosa* or *Aspergillus*. Septic arthritis, cellulitis, and osteomyelitis are also observed and are usually caused by *S. aureus*, although other bacterial pathogens have also been found. Patients can have chronic mucocutaneous candidiasis and occasionally exhibit keratoconjunctivitis, sometimes complicated by corneal scarring. One feature noted in the majority of patients by the time they reach the teenage years is the presence of coarse facial features (broad nasal bridge, prominent nose). Dental and bone abnormalities are also common features of HIES. Delayed or failure to shed primary teeth occur in the majority. Hyperextensible joints and scoliosis are frequent. Osteopenia of unknown etiology is observed in most patients, and there is an increased risk of fractures to the long bones and vertebral bodies even in the absence of osteopenia. Vascular disease, including aneurysms, tortuosity of middle-sized arteries, and hypertension, is also frequently seen.

Diagnosis

The diagnosis of STAT3-HIES should be entertained in any child or young adult who has the above-described clinical picture or simply a history of recurrent infections. The hallmark laboratory finding is a marked elevation of serum IgE, almost always greater than 2500 IU/mL. Levels can be as high as 150,000 IU/mL. Most patients also have peripheral eosinophilia. However, there is no correlation of clinical disease activity with the level of either IgE or peripheral eosinophilia. Atopic dermatitis is the major differential diagnosis because comparably high serum levels of IgE can be seen in patients in this disorder, as well as superficial skin infections. The severe and recurrent nature of the staphylococcal furuncles and pneumonias usually seen in HIES can help distinguish these patients from those with atopic dermatitis. Patients with other primary immunodeficiency syndromes may also manifest elevated IgE levels. Scoring criteria predictive of STAT3 mutations, including recurrent pneumonia, pathologic bone fractures, and lack of Th17 cells, are helpful.[22] DNA testing of STAT3 should be used to make a definitive diagnosis; there are also rare patients who phenocopy STAT3-HIES but have mutations in pathway-related genes.

Therapy

The therapy for STAT3-HIES is largely supportive.[22] Treatment emphasizes prevention of end-organ complications by using antimicrobial prophylaxis and aggressive treatment of infections. Prophylactic antibiotics (e.g., dicloxacillin or TMP-SMX) can be effective in preventing *S. aureus* infections. Dermatitis can be treated with topical steroids. Bathing in diluted bleach can diminish colonization by *S. aureus*. Prophylactic antifungals can be helpful in patients with chronic mucocutaneous candidiasis. Intravenous antibiotics are used for deep-seated infections or for resistant cutaneous infections. Surgical resection of persistent pneumatoceles is sometimes indicated to prevent superinfection by fungal and gram-negative organisms. Intravenous Ig infusions have shown some success in the management of HIES. Attention should also be paid to blood pressure and other vascular complications. Although a role for HSCT in STAT3-HIES is unclear, two children with STAT3 mutations who underwent transplantation for non-Hodgkin lymphoma are alive 10 and 14 years later with resolution of all immunologic and nonimmunologic features of HIES.[22]

Miscellaneous Chemotactic Disorders

It is extremely rare to have primary defects in neutrophil actin polymerization as a cause of abnormal chemotaxis and recurrent infections.[2,3] An apparent AR disorder of actin polymerization has been described in a male infant of Tongan descent who presented with severe skin infections, recurrent pulmonary infiltrates, thrombocytopenia, and invasive *Candida tropicalis* infection (MIM %257150). Neutrophil actin polymerization was markedly abnormal and associated with increased expression of the actin-binding protein LSP-1. In another single case, a heterozygous point mutation in β-actin affecting binding to actin-regulatory proteins was discovered in a female patient with recurrent infections, photosensitivity, and mental retardation. Neutrophils had a marked impairment in chemotaxis and in the formyl peptide-induced respiratory burst. Finally, the use of unbiased exome sequencing has identified the genetic basis for several "actinopathies" due to defects in various actin regulatory proteins, resulting in impaired chemotaxis of neutrophils and other immune cells.[23] Affected patients suffer from recurrent bacterial and other infections, but each disorder also has distinctive laboratory and clinical features. For example, in patients with genetic defects in the actin-binding protein WDR1, which is important for depolymerizing actin via cofilin, about 50% of neutrophils show herniation of the nuclear lobes, which colocalize with increased F-actin staining. These patients also often have severe stomatitis resulting in acquired microstomia and oral stenosis.

A syndrome of severe neutrophil dysfunction caused by a DN mutation in Rac2, a small GTPase expressed in blood cells that acts in many signal transduction pathways, was described in an infant boy born to unrelated parents (see Dinauer and Newburger[3]). This baby presented with rapidly progressive and deep-seated soft tissue infections, along with neutrophilia and poor formation of pus. The clinical phenotype resembles LAD, but there is normal expression of β2 integrins and fucosylated proteins. Neutrophils had marked defects in actin polymerization, chemotaxis, degranulation, and the respiratory burst in response to chemoattractants. Neutrophil responses to other agonists were normal, suggesting that the DN Rac2 mutation produces a selective intracellular signaling defect.

Localized juvenile periodontitis (LJP) is a heterogeneous disorder of unknown etiology characterized by chronic and recurrent periodontal infections and severe alveolar bone loss with onset at the time of puberty.[24] Many patients with LJP have been reported to have defective neutrophil chemotaxis in vitro. At present, it appears that LJP is an acquired disorder in some patients and a genetic disorder in others. It may also be a combination of both in certain patients because they may inherit an unusual sensitivity to the chemotactic inhibitors released by certain periodontal microorganisms. The diagnosis of the disorder is made on the basis of severe periodontal disease and destructive alveolar bone loss involving the first molars and incisors developing during adolescence. It is important to note that many qualitative and quantitative neutrophil disorders are also associated with severe periodontal disease. Therefore the differential diagnosis should include neutropenia (both chronic and cyclic), LAD, CGD, and Chédiak-Higashi syndrome (CHS).

One of the most consistently observed chemotactic abnormalities is seen in neonatal neutrophils.[25] These cells exhibit impaired chemotaxis in vitro in response to a wide variety of chemotactic factors. It appears as though this abnormality is caused, at least in part, by defects in cellular adhesion as a result of diminished mobilization of intracellular adhesion-promoting molecules to the cell surface. Defective neutrophil chemotaxis can be seen in normal neonates between birth and 5 days of age. In severely ill infants, the defect may persist for a longer time.

DEFECTS IN THE STRUCTURE AND FUNCTION OF LYSOSOMAL GRANULES

Two major disorders of neutrophil granules have been described, CHS and specific granule deficiency (SGD). A great deal has been learned about the structural and functional abnormalities of neutrophils from patients with these conditions. Although rare, these disorders are also obligatory components in the differential diagnosis for any patient with recurrent bacterial and fungal infections.

Chédiak-Higashi Syndrome

CHS is a rare AR, multisystem disease resulting from widespread defects in granule morphogenesis, with giant lysosomes in leukocytes and other cells throughout the body.[26] The disorder is characterized by partial oculocutaneous albinism, frequent (and sometimes fatal) bacterial infections, a mild bleeding diathesis, and peripheral as well as cranial neuropathies associated with defects at the optic chiasm. Those who survive the recurrent infections develop an "accelerated phase" of the disease; one of the hereditary forms of HLH (see Chapter 53), which, if untreated, is eventually fatal because of a profound pancytopenia that develops.

The most dramatic granule defects are manifested in the various blood cells. Neutrophils contain a highly inhomogeneous population of huge granules derived from coalescence of azurophilic (primary) granules. The giant granules are often more prominent in the BM than in the peripheral blood because many of the abnormal myeloid precursors are apparently destroyed before they leave the BM, resulting in moderate neutropenia with absolute neutrophil counts ranging from 500 to 2000 cells/mm^3. Granules are also markedly deficient in antimicrobial granule enzymes such as cathepsin G and elastase, consistent with a defect in granule morphogenesis. Degranulation is delayed and incomplete in Chédiak-Higashi neutrophils, resulting in impaired bacterial killing. Chemotaxis is also defective, perhaps related to poor deformability because of the presence of the large granules. Monocytes and macrophages exhibit similar giant cytoplasmic granules, with resultant abnormalities in their phagocytic functions. Giant granules are also seen in lymphocytes and are associated with defects in cytotoxic T-lymphocyte and NK cell function. Eosinophils contain large granules, the functional significance of which is not known. Platelets in this disorder have a storage pool deficiency of adenosine diphosphate and serotonin, presumably caused by the abnormal granule morphogenesis in megakaryocytes, leading to a defect in platelet aggregation.

Abnormal giant granules are also present in other cell types. These include melanocytes, which contain abnormal melanosomes that cannot transfer their contents to adjacent keratinocytes; Schwann cells; astrocytes; and certain cells in the liver, spleen, pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.

Molecular Genetics

A gene termed *CHS1* or *LYST* (for its presumed function as a lysosomal trafficking regulatory protein) is affected in the majority of CHS cases and is on the long arm of chromosome 1.[26] The encoded protein is very large (3801 amino acids); its specific function is unknown, but recent studies suggest that it may inhibit lysosome fusion with other intracellular membrane vesicles. A variety of frameshift and nonsense mutations that predict synthesis of truncated forms of the protein have been identified in most, but not all, CHS patients studied to date. There is no correlation between the length of the truncated CHS1 protein and the severity of the disease. Disorders similar to human CHS have also been described in many mammalian species, including Aleutian mink, *beige* mice, blue foxes, cats, killer whales, and Hereford cattle. Identification of the human CHS1 gene was aided by positional cloning of the mouse *lyst* homolog affected in *beige* mice.

Clinical Manifestations

The key features of CHS are summarized in Table 51.9. The disease usually presents in infancy or early childhood, with infections involving the lungs, skin, and mucous membranes being most commonly encountered. Dental caries and periodontal disease are also common.[21] The most frequent offending organism is *S. aureus*. Gram-negative bacteria, *Aspergillus* spp., and *Candida* spp. also are responsible for many infections. Platelet granule defects result in easy bruising and epistaxis. There is partial oculocutaneous albinism and photosensitivity. Patients may have a white forelock or an ashen or grayish silver sheen to the hair, which can vary from blond to dark brown. In younger patients, there may be a cartwheel distribution of pigment in the iris and an abnormal red reflex. Neurologic manifestations include peripheral or cranial neuropathies, gait abnormalities, muscle weakness, sensory loss, seizures, or spinocerebellar degeneration. Neurologic symptoms worsen with age.

Approximately 85% of children surviving into the second decade of life develop an accelerated phase of the disease, with fever, lymphadenopathy, and progressive pancytopenia, that is now recognized to be a genetic form of HLH caused by impaired lymphocyte and NK cell function.[27] The development of HLH can sometimes be precipitated by Epstein-Barr virus infection. A reactive-appearing lymphohistiocytic proliferation occurs in the liver, spleen, lymph nodes, and BM, and the prognosis is uniformly fatal unless patients undergo BMT.

Diagnosis

The diagnosis of CHS is made on the basis of the giant peroxidase-positive lysosomal granules in the peripheral blood granulocytes or in BM myeloid cells. Identification of large, acid phosphatase–positive lysosomes in amniocytes and chorionic villus cells has been used to diagnose CHS prenatally. Other clinical features characteristic of

TABLE 51.9 **Summary of Chédiak-Higashi Syndrome**

Incidence	More than 200 cases described
Inheritance	AR
Molecular defect	A defect in granule morphogenesis in multiple tissues resulting from mutations in the *CHS1 (LYST)* gene encoding a lysosomal trafficking regulator protein
Pathogenesis	Giant coalesced azurophil granules in neutrophils, resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis; abnormal granules in other cells (NK cells, cytotoxic T cells, platelets, melanocytes, neurons)
Clinical manifestations	Partial oculocutaneous albinism Recurrent severe bacterial infections (usually *Staphylococcus aureus*) Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss) HLH (accelerated phase)
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in BM myeloid progenitor cells Widespread lymphohistiocytic infiltrates in accelerated phase
Differential diagnosis	Other genetic forms of partial albinism Giant granules can be seen in acute and CMLs
Therapy	Prophylactic TMP-SMX Parenteral antibiotics for acute infections Ascorbic acid (200 mg/day for infants; 6 g/day for adults) HSCT before or at beginning of HLH
Prognosis	Most patients die from infection or complications of HLH during the first or second decade of life unless transplantation is performed

AR, Autosomal recessive; *BM*, bone marrow; *CML*, chronic myeloid leukemia; *HLH*, hemophagocytic lymphohistiocytosis; *HSCT*, hematopoietic stem cell transplant; *NK*, natural killer; *TMP-SMX*, trimethoprim-sulfamethoxazole.

CHS can support the diagnosis, including mild oculocutaneous albinism; silvery hair, in which microscopic examination reveals giant melanin granules; and a bleeding diathesis. The development of HLH is characterized by diffuse infiltrates of lymphohistiocytic cells seen on biopsy and by pancytopenia (see Chapter 53). Occasionally, giant granules that resemble those of CHS can be seen in both acute and chronic myelogenous leukemias.

Therapy

The treatment for the stable phase of CHS is similar to that for other neutrophil disorders. Prophylactic antibiotics such as TMP-SMX appear to be beneficial. Parenteral antibiotics are indicated for acute infections, and responses are often slow. Treatment with high-dose ascorbic acid (200 mg/day for infants; 6 g/day for adults) has been found to improve the clinical status of some patients. Although there is some controversy regarding the efficacy of ascorbic acid, given the safety of this medication, it seems prudent to administer it to all patients. The treatment of HLH (accelerated phase) includes combinations of drugs that suppress the function of activated macrophages and T cells followed by allogeneic HSCT.[27] Indeed, transplantation is ideally performed before or at the beginning of the accelerated phase. Note that transplantation does not prevent the progressive neuropathy of CHS.

Specific Granule Deficiency

Neutrophil SGD is an extremely rare congenital disorder characterized by recurrent bacterial and fungal infections, primarily involving the skin, ears, and lungs.[3,28] Infections are often indolent and smoldering, and *S. aureus*, *P. aeruginosa*, enteric gram-negative bacteria, and *C. albicans* are the major pathogens. Family studies suggest that it is inherited in an AR manner. Neutrophils from patients with SGD have atypical bilobed nuclei, absent specific granules, and multiple deficiencies of secondary and tertiary granule mRNAs and proteins, including lactoferrin, vitamin B_{12}–binding protein, and gelatinase B; although azurophil granules in this disorder are present and contain MPO and lysozyme, they are markedly deficient in defensins. Monocytes display cell surface and functional defects, eosinophils lack eosinophil-specific granule proteins such as eosinophil cationic protein, and platelets have abnormal α granules, suggesting that the underlying defect may be related to regulation of the synthesis of certain granule and membrane proteins. This defect in synthesis is confined to BM-derived cells because lactoferrin secretion is normal in the glandular epithelia of SGD patients despite the severe deficiency in the neutrophils.

The recurrent skin and pulmonary infections characteristic of SGD appear to be caused by two fundamental defects in the neutrophils. One defect is the marked deficiency of at least two important microbicidal granule proteins, lactoferrin and defensins. The other defect is a relatively severe chemotactic abnormality presumably caused by the absence of the intracellular pool of leukocyte adhesion molecules that normally resides in the specific granules. As discussed earlier, these β2 integrins play a key role in phagocyte chemotaxis.

The molecular defect responsible for most cases of SGD has recently been shown to involve a myeloid transcription factor known as C/EBPε, which regulates expression of certain genes activated during granulocyte differentiation.[3,28] This came about serendipitously when it was recognized that mice with a targeted deletion in the C/EBPε gene displayed characteristics similar to those of SGD patients, including neutrophils with bilobed nuclei, absent secondary granules, and impaired chemotaxis along with increased susceptibility to bacterial infections. To date, mutations in the C/EBPε gene have been identified in two SGD patients that encode truncated, nonfunctional proteins. However, DNA sequencing of the C/EBPε gene of several other SGD patients has not revealed abnormalities, suggesting that SGD is a genetically heterogeneous disorder.

The diagnosis of SGD can be readily made by microscopic examination. Wright-stained neutrophils are devoid of specific granules but contain normal numbers of azurophilic granules. Electron microscopy reveals small peroxidase-negative vesicles, which presumably represent empty specific granules. The diagnosis of SGD can also be established by demonstrating a severe deficiency in either lactoferrin or vitamin B_{12}–binding protein. An acquired form of SGD can be seen in burn patients or in individuals with various myeloproliferative neoplasms. The treatment for SGD is similar to that for other neutrophil disorders. If medical management is aggressive, the prognosis appears quite good, with patients surviving into their adult years.

MISCELLANEOUS INHERITED AND ACQUIRED DISORDERS OF PHAGOCYTE FUNCTION

Rare inherited defects in phagocyte production or response to inflammatory cytokines are manifested as recurrent infections.[14,29] HIES also falls into this category (see earlier discussion). A distinctive group of disorders referred to as *mendelian susceptibility to mycobacterial diseases* (MSMD) involves inherited defects in macrophage IL-12/23–dependent IFN-γ–mediated immunity. Macrophage production of IL-12 and IL-23 after ingestion of mycobacteria triggers IFN-γ production by T and NK lymphocytes, which in turn activates crucial genes in macrophages. MSMD (MIM 20990) can be caused by inherited AR, autosomal dominant (AD), or X-linked defects leading to impaired T-cell production of IFN-γ, expression of the IFN-γ receptor, or downstream signaling, which results in a spectrum of recurrent and severe atypical mycobacterial infections, as well as susceptibility to *Salmonella* and, in some subgroups, viral infections.[14,29] As mentioned earlier, recessive point mutations in X-linked *CYBB* that selectively impair expression of the NADPH oxidase subunit gp91^{phox} in macrophages but not neutrophils are also considered a subgroup of MSMD.[14] A variety of genetic defects in a scaffolding protein known as IKK-γ or NEMO that is important for activation of the nuclear factor kappa-B (NF-κB) signaling pathway have been reported in patients with anhydrotic ectodermal dysplasia and immunodeficiency; affected children have recurrent pyogenic infections with a minimal systemic inflammatory response and can also develop opportunistic infections with atypical mycobacteria or *Pneumocystis carinii*.[14] Several other kindred have been described with genetic deficiency of another protein, IRAK-4, important for NF-κB activation by pyogenic bacteria via the Toll-like receptor/IL-I receptor superfamily. Affected children also had recurrent infections with *S. pneumonia* and *S. aureus* and a poor inflammatory response but no dysmorphic features or opportunistic infections. Finally, with the increasing use of low-cost gene sequencing, it is likely that new inherited disorders of phagocyte function will continue to be identified in the coming years.[29]

Patients with glycogen storage disease type Ib (GSD-Ib), which results from absence of a glucose-6-phosphate transporter, have impaired neutrophil functions and neutropenia (see Chapter 54).[30] Neutrophil defects include depressed chemotaxis, phagocytosis, and NADPH oxidase activity. Although neutropenia appears to result from increased neutrophil apoptosis, how impaired glucose homeostasis leads to abnormal neutrophil function is uncertain. Interestingly, the BM in the face of neutropenia shows marked hypercellularity with increased mature neutrophils in some patients. The neutrophil count increases within hours of granulocyte colony-stimulating factor (G-CSF) administration, suggesting it is acting in part by releasing neutrophils from the BM. GSD-Ib patients can have infections as well as inflammatory bowel disease. Therefore, in addition to management of the metabolic disruption, these patients are also often treated with G-CSF to improve neutropenia.

There are a variety of noncongenital defects in phagocyte function that can be associated with an increased risk of bacterial or fungal infection.[2,3] Several have already been mentioned, including neonatal neutrophil dysfunction manifested as poor adhesion and chemotaxis. Patients with myelodysplastic syndromes and acute nonlymphoblastic lymphoma can have subpopulations of neutrophils variably defective in adhesion, migration, and production of reactive oxidants, and microbicidal activity that has correlated with an increased risk of infection. Similar defects have been described in diabetes mellitus, Gaucher disease, and renal failure. Severe bacterial infections, surgical trauma, and severe burns can also result in transient depression of a variety of neutrophil functions. The underlying mechanism(s) are incompletely defined and may be related to effects of high levels of inflammatory mediators produced in response to infection or trauma or to products released by bacteria.

CHAPTER 52

CONGENITAL DISORDERS OF LYMPHOCYTE FUNCTION

Sung-Yun Pai and Luigi D. Notarangelo

Over 350 molecular defects that result in primary immune deficiency are known to date.[1,2] Many of these gene defects have been identified in recent years with the advent of whole-exome and whole-genome sequencing. The study of patients with primary immune deficiencies has unraveled fundamental mechanisms that govern lymphocyte development and function. Importantly, characterization of the molecular basis of these diseases has revealed unanticipated heterogeneity of the clinical and immunological phenotype. This chapter reviews disorders of thymus organogenesis, severe combined immune deficiency (SCID), other combined immunodeficiencies, disorders with immune dysregulation, and defects of humoral immunity.

DEFECTS OF THYMUS ORGANOGENESIS

The thymus is the primary organ where T lymphocytes are generated and educated. Endoderm-derived thymic stem cells derived from the third pharyngeal pouch differentiate into cortical and medullary epithelial cells, which in turn induce the differentiation of hematopoietic precursors into T cells. Thus, defects of thymus organogenesis have important consequences on immune function.

DiGeorge Syndrome

DiGeorge syndrome (DGS) is caused by developmental anomalies of the third and fourth pharyngeal pouches, and is characterized by thymic hypoplasia, hypoparathyroidism, conotruncal heart malformations, which are a group of congenital cardiac outflow tract anomalies that include such defects as tetralogy of Fallot, pulmonary atresia with ventricular septal defect, double-outlet right ventricle, double-outlet left ventricle, truncus arteriosus and transposition of the great arteries, interrupted aortic arch type B among others, and facial dysmorphisms (micrognathia, hypertelorism, antimongoloid slant of the eyes, cleft palate, and ear malformations).[3] Hypocalcemic seizures are common. Feeding problems, microcephaly, speech delay, neurobehavioral problems (including bipolar disorders, autistic spectrum disorders, and schizophrenia later in life), and scoliosis are frequently observed.

Between 50% and 90% of patients with DGS carry a hemizygous deletion of chromosome 22q11, which occurs in ~1:3000 newborns, most arising de novo. Fluorescent in situ hybridization (FISH) and multiplex ligation-dependent probe amplification (MLPA) readily identify the 22q11del in most cases. More rarely, DGS is associated with mutations of the *TBX1* gene, contained within the 22q11 interval, or with 10p deletion.

Most patients have "partial DGS," manifested by mild T-cell lymphopenia and immunodeficiency. Such patients may be asymptomatic, may have oral thrush and recurrent infections, or may develop autoimmune disease such as juvenile idiopathic arthritis, immune thrombocytopenic purpura, and Raynaud phenomenon. Approximately 1% of DGS patients have "complete DGS," with absence of circulating T cells. Some DGS patients may develop low numbers of oligoclonal T lymphocytes that undergo activation in vivo and infiltrate target tissues, causing skin rash, liver dysfunction, and lymphadenopathy. This condition is known as complete atypical DGS.

Treatment of DGS includes correction of severe heart defects, and supplementation with calcium and vitamin D to correct the hypocalcemia.[3] If a significant immune defect is present, prophylaxis of *Pneumocystis jiroveci* pneumonia with trimethoprim-sulfamethoxazole (TMP-SMZ) is indicated. Live-attenuated vaccines can be safely administered to patients with partial DGS who have good cellular immunity (with CD8$^+$ count >300 cells/μL); however, these vaccines are contraindicated in patients with complete DGS. Use of immunosuppressive drugs is indicated in patients with complete atypical form of the disease.

Ultimately, survival in patients with complete DGS requires immune reconstitution. Stem cell transplantation from human leukocyte antigen (HLA)-identical donors may allow engraftment of mature T cells contained in the graft. However, because of the absence of thymic tissue, newly developed T cells are not generated, and the patient may remain susceptible to pathogens that are not recognized by donor-derived T cells contained in the graft.

By contrast, thymic transplantation represents the treatment of choice for patients with complete DGS, including the atypical variant.[4,5] The thymus obtained as discarded tissue from unrelated infants undergoing heart surgery is sliced and cultured in vitro, then implanted in the quadriceps muscles of the infant. In most cases, naïve T cells appear at around 4 to 7 months of age; these cells are tolerant to donor thymic cells, display a polyclonal repertoire, and have normal proliferative capacity. Although the number of CD3+ T cells in transplanted patients often remains lower than normal, their diversity and function are sufficient to prevent life-threatening infections. The success of this treatment has recently led to approval of this therapy by the Food and Drug Administration in the United States.

FOXN1 Deficiency

The transcription factor FOXN1 (whose gene is mutated in the *nude* mouse) plays a critical role in thymus and eccrine glands development. *FOXN1* mutations in humans cause athymia, profound T-cell lymphopenia, alopecia totalis, and nail dystrophy.[6] Similar to DGS, reconstitution of T-cell immunity can be achieved with thymic transplantation.[4,5] FOXN1 haploinsufficiency may also cause T-cell lymphopenia at birth, followed by gradual and partial recovery of T-cell count.

CHARGE Syndrome

This syndrome is characterized by the association of coloboma (a hole in one of the structures of the eye, such as the iris, retina, choroid, or optic disc), heart anomalies, choanal atresia, mental retardation, genital and ear anomalies, and immunodeficiency. Most cases are sporadic and represent de novo mutations of the *CHD7*[7] or of the *SEMA3E* genes.[8] The immunodeficiency is secondary to defects of thymic development. There is a variable degree of T-cell lymphopenia, which in some cases is very severe, resembling SCID.

PAX1 Deficiency

Paired Box 1 (PAX1) is a transcription factor involved in early stages of pharyngeal pouch differentiation and thymus development. Autosomal recessive PAX1 deficiency is characterized by T-cell lymphopenia associated with facial anomalies, hearing loss, vertebral anomalies and neurodevelopmental problems.[9]

SEVERE COMBINED IMMUNE DEFICIENCY DUE TO EARLY DEFECTS IN T-LYMPHOCYTE DEVELOPMENT

SCID, the most severe form of congenital immunodeficiency, is caused by defects that completely abrogate the development of T lymphocytes, and in some cases also B and/or natural killer (NK) lymphocytes. Advances in the genes responsible, newborn screening, and gene therapy have had a strong impact on the diagnosis and therapy of SCID.

Pathobiology and Genetics

Genetic defects that cause SCID affect various stages in T-cell development (Fig. 52.1), and can be grouped into three major categories: (1) defects in cytokine receptor signaling; (2) defects in lymphocyte survival; and (3) defects of expression and function of the pre–T-cell receptor

Cytokine Receptor Signaling Defects

The most common form of SCID in humans is the X-linked form due to mutations of the *IL2RG* gene, which encodes for the common gamma chain (γc).[10,11] This protein is shared by receptors for interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21, and signals through the intracellular kinase Janus-activated kinase (JAK)3. Patients with mutations in *IL2RG* or *JAK3* lack both T and NK cells, since development of these subsets depends on IL-7- and IL-15-mediated signaling, respectively. B lymphocytes are present but antibody production is impaired because of the lack of T cells and defective signaling through the IL-21R.[12]

Defects in Lymphocyte Survival

Proliferation and survival of lymphoid progenitor cells are essential to permit generation of a normal number of mature lymphocytes. Some forms of SCID are associated with increased apoptosis. Adenosine deaminase (ADA) converts adenosine to inosine (and deoxyadenosine to deoxyinosine). In patients with ADA deficiency, accumulation of toxic phosphorylated derivatives of deoxyadenosine causes cell death and results in extreme lymphopenia, with virtual absence of T, B, and NK lymphocytes.[13,14] Reticular dysgenesis (RD) is a form of SCID characterized by the association of severe lymphopenia, agranulocytosis, and sensorineural deafness (see Chapter 30). RD is caused by defects in adenylate kinase 2 (AK2), resulting in increased sensitivity to reactive oxygen species and increased apoptosis.[15,16]

Defects of Expression and Signaling Through the Pre–T-Cell Receptor and the T-Cell Receptor

Rearrangement of the T-cell receptor (TCR) genes by means of variable diversity joining (V(D)J) recombination allows expression of the pre-TCR (composed of the pre-Tα and the TCRβ chain), and of mature forms (TCRαβ and TCRγδ) of the TCR.

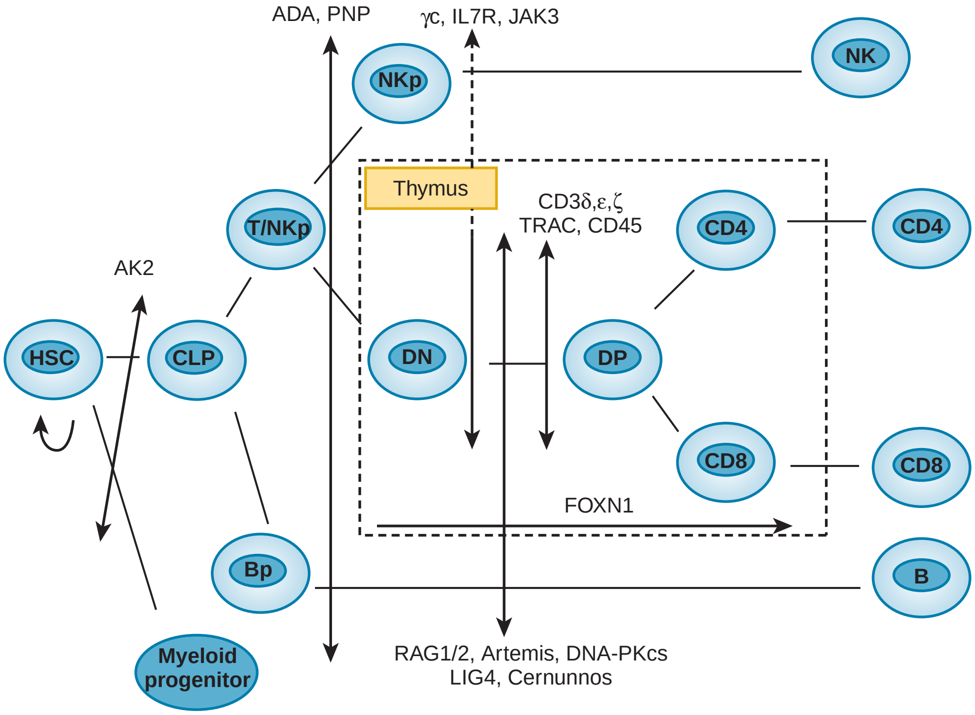

Figure 52.1 GENETIC DEFECTS ASSOCIATED WITH SEVERE COMBINED IMMUNE DEFICIENCY (SCID). Schematic representation of blocks (*arrows*) in lymphoid development associated with genetic defects responsible for SCID. Dashed line indicates that the generation of NK lymphocytes is compromised in γc and JAK3 deficiency, but not in IL7R deficiency. *ADA*, Adenosine deaminase; *AK2*, adenylate kinase 2; *B*, B-cell; *Bp*, B-cell progenitor; *CLP*, common lymphoid progenitor; *DN*, double-negative thymocyte; *DNA-PKcs*, DNA protein kinase catalytic subunit; *DP*, double-positive thymocyte; *FOXN1*, forkhead box N1; *γc*, common gamma chain; *HSC*, hematopoietic stem cell; *IL7R*, interleukin-7 receptor; *JAK3*, Janus-associated kinase 3; *LIG4*, DNA ligase IV; *NK*, natural killer cell; *NKp*, natural killer cell progenitor cell; *PNP*, purine nucleoside phosphorylase; *RAG*, recombinase activating gene; *T/NKp*, common progenitor of T and natural killer lymphocytes; *TRAC*, T-cell receptor alpha constant chain.

The lymphoid-specific recombinase-activating genes (*RAG1* and *RAG2*) proteins initiate V(D)J recombination by recognizing recombination-specific sequences that flank the V(D)J elements of the TCR and of immunoglobulin genes, introducing DNA double-strand breaks. These are then repaired through the ubiquitously expressed nonhomologous end-joining (NHEJ) pathway. Mutations of the *RAG1* and *RAG2* genes, and genes that encode for Artemis, DNA ligase IV, and DNA-protein kinase catalytic subunit (all components of the NHEJ pathway), result in SCID with a lack of T and B lymphocytes (see Figs. 52.1 and 52.2), but normal numbers of NK lymphocytes.[17–20] Mutations of the *NHEJ1* gene (encoding Cernunnos/XLF, another component of the NHEJ pathway) severely impair, but do not completely abrogate, T- and B-cell development.[21] Because NHEJ is involved in general mechanisms of DNA repair involving nonlymphoid cells, patients with defects of this pathway also show increased radiation sensitivity, are at a higher risk of tumors. In addition, neurologic problems are common, except in patients with Artemis deficiency.

Signaling through the pre-TCR/CD3 complex is essential to promote progression from $CD4^-CD8^-$ double-negative (DN) to $CD4^+CD8^+$ double-positive (DP) stage of thymocyte development. Mutations of the CD3δ (*CD3D*), CD3ε (*CD3E*), and CD3ζ (*CD3Z*) chains interfere with this process and result in SCID.[22–24] In contrast, mutations of CD3γ (*CD3G*) are more often associated with a milder phenotype that includes autoimmunity.[25] Downstream of the TCR/CD3 complex, mutations of the Linker for Activation of T cells (LAT), also perturb signaling and cause $T^- B^+$ SCID.[23] Finally, mutations of the CD45 phosphatase, also involved in cell signaling, cause $T^- B^+$ SCID.[26]

Clinical and Laboratory Manifestations

Typical clinical features of SCID include early-onset severe infections caused by bacteria, viruses, fungi, and opportunistic pathogens (including *P. jiroveci* pneumonia), protracted diarrhea, candidiasis, and failure to thrive. Engraftment of maternally derived T lymphocytes is common in SCID.[27] The patient may be asymptomatic or may present with symptoms similar to graft-versus-host disease (GVHD): skin rash, elevation of liver enzymes, diarrhea, and cytopenias. Hypomorphic mutations in SCID-causing genes may lead to residual development of T cells that undergo peripheral expansion and infiltrate target organs, causing various symptoms (erythroderma, diarrhea, hepatosplenomegaly, lymphadenopathy, diarrhea). This clinical phenotype is also known as *Omenn syndrome*.[28]

Some forms of SCID may present with additional clinical features (see earlier section on Defects in Thymic Development). In patients with ADA deficiency, accumulation of toxic metabolites may cause cupping and flaring of the ribs, liver dysfunction, sensorineural deafness and neurobehavioral problems. Microcephaly is often seen in forms of SCID associated with radiosensitivity and impairment of DNA double-strand break repair. Sensorineural deafness is observed in RD.

A family history (including consanguinity, deaths in infancy, and the gender of other affected family members) may be suggestive of X-linked versus autosomal recessive inheritance patterns. Measurement of absolute lymphocyte count (ALC) and the absolute number of $CD3^+$ T cells, $CD4^+$ and $CD8^+$ T-cell subsets, $CD19^+$ B cells, and NK cells ($CD16^+/CD56^+$ NK lymphocytes) confirms the diagnosis and may direct the work-up towards specific gene defects. The presence of $CD3^+$ cells in a child with clear clinical manifestations of SCID may indicate maternal T-cell engraftment or may be due to hypomorphic mutations that allow residual T-cell development. In both of these situations, the T cells have an activated/memory ($CD45RO^+$), whereas T cells in normal infants are predominantly naive ($CD45RA^+$). In vitro proliferative responses to mitogens are drastically reduced in patients with SCID, but may be partially preserved in infants with Omenn syndrome. A chest X-ray with a lack of a thymic shadow supports the diagnosis of SCID. Serum IgA and IgM levels are low to undetectable, but IgG levels may be normal early in life, reflecting the transplacental passage of maternally derived antibodies. (See box on Diagnostic Approach to Severe Combined Immune Deficiency.)

DIAGNOSTIC APPROACH TO SEVERE COMBINED IMMUNE DEFICIENCY

- SCID presents early in life with severe infections of bacterial, viral, or fungal origin.
- Opportunistic infections are common in infants with SCID.
- Respiratory infections, protracted diarrhea, and failure to thrive are typical signs at presentation.
- Lymphopenia is present in 50%–70% of infants with SCID. Age-specific norms must be used in evaluating the ALC since infants and children have much higher ALCs than adults (3500–13,000 in very young infants versus 1000–2800 in adults).
- T-cell lymphopenia is the hallmark of the disease; abnormalities of the absolute number of B and NK lymphocytes are observed in some forms of SCID. However, T lymphocytes may be present in SCID infants with maternal T-cell engraftment or with hypomorphic mutations in SCID-associated genes that allow residual T-cell development. Thus, a normal ALC does not rule out SCID.
- Maternally engrafted T cells proliferate in the infant with SCID in vivo, but the vast majority do not proliferate in vitro when stimulated with traditionally used mitogens such as concanavalin A and phytohemagglutinin, as measured by thymidine incorporation. Thus, if SCID is suspected, but T cells are detectable, maternal engraftment studies and proliferation to mitogens must be evaluated.
- Universal newborn screening for SCID, based on enumeration of TRECs by quantitative PCR, has been implemented in the United States and in several other countries worldwide. TRECs are high in newly generated T cells and low when T cells are absent or when maternally engrafted T cells are present.
- SCID is genetically heterogeneous. The most common form in Western countries is inherited as an X-linked trait and is $T^-B^+NK^-$.
- The lack of all lymphocytes ($T^-B^-NK^-$ SCID) is highly suspicious for ADA deficiency, in which accumulation of toxic metabolites results in death of all lymphocytes. The diagnosis can be confirmed by testing of ADA enzymatic activity and of intracellular levels of phosphorylated derivatives of deoxyadenosine.

Diagnosis by Universal Newborn Screening

SCID can be diagnosed at birth by measuring levels of TCR excision circles (TRECs). TRECs are a byproduct of V(D)J recombination and are present as circularized DNA fragments in newly generated, naïve T lymphocytes that express the αβ form of the TCR. Levels of TRECs in circulating lymphocytes are particularly high in newborns and infants, and can be detected by polymerase chain reaction (PCR) amplification of DNA extracted from the Guthrie card.[29] Newborn screening for SCID was recommended to be added to the standard panel in the United States in 2010, and as of December 2018 all 50 states were screening for SCID. Based on screening of ~3,000,000 infants in the United States, the incidence of SCID is now estimated to be 1 in 58,000 births, higher than with clinical screening alone.[30] Many other countries in the world are also screening.[29]

SCID is not the only cause for low TREC levels at birth; other conditions include prematurity, loss of lymphocytes in the third space (such as in babies with chylothorax) as well as various other syndromes. Enumeration of the absolute lymphocyte count and of lymphocyte subsets (including naïve and memory T cells) should be part of the laboratory work-up following a positive newborn screening concerning for SCID. Ultimately, genetic tests may reveal the molecular basis of the disease.

Prognosis, Therapy, and Future Directions

Supportive Management

Management of SCID includes observance of strict hygiene measures, prevention of *P. jiroveci* pneumonia with TMP-SMZ, prompt investigation and aggressive treatment of infections, immunoglobulin replacement, and adequate support with enteral or parenteral nutrition. Infections caused by cytomegalovirus (CMV; causing interstitial pneumonia, hepatitis and/or gastroenteritis) and Epstein-Barr virus (EBV; causing lymphoproliferative disease) require active surveillance and preemptive therapy. To prevent transmission of viral infections, blood products from CMV-seronegative donors or leukofiltered products should be used and must be irradiated to prevent transfusion-associated GVHD. Immunosuppression with steroids and cyclosporine A may be needed to treat GVHD-like manifestations associated with Omenn syndrome or maternal T-cell engraftment. Administration of live vaccines must be avoided in infants with SCID. In spite of these measures, SCID is inevitably fatal within the first few years of life, unless immune reconstitution is achieved with treatment.

In most cases, definitive treatment of SCID requires hematopoietic cell transplantation (HCT). Enzyme-replacement therapy (ERT), with weekly intramuscular injection of pegylated recombinant ADA which allows conversion of adenosine and deoxyadenosine to inosine and deoxyinosine, respectively, thus preventing accumulation of toxic phosphorylated derivatives. This treatment leads to improvement of lymphocyte counts and of immune function. Disadvantages of ERT include expense, as it must be continued indefinitely, waning of therapeutic effect over time, and the development in some patients of neutralizing antibodies to polyethylene glycol-modified adenosine deaminase (PEG-ADA).

General Principles of Stem Cell Transplantation for Severe Combined Immune Deficiency

Stem cell transplantation (SCT) is the standard treatment that promotes long-term immune reconstitution in infants with SCID. SCT for other conditions is generally performed with chemotherapy or radiation conditioning, to prevent graft rejection and eliminate or reduce host hematopoietic stem cells (HSCs), favoring donor hematopoiesis.[31] Because of the lack of T lymphocytes, infants with SCID are considered to have an inherent inability to reject the graft, and may therefore receive SCT from an HLA-identical related donor (sibling) without conditioning and with no need for GVHD prophylaxis.[32] With this approach, expansion of mature T cells present in the donor bone marrow allows rapid improvement of T-cell count; newly generated naïve T cells derived from donor HSCs appear on average 3 to 4 months after transplant.

Unconditioned SCT may also be performed from mismatched related donors (parent), with T-cell depletion of the graft and post-transplant prophylaxis to prevent GVHD. In this case, the appearance of peripheral T cells is entirely dependent on intra-thymic differentiation of donor-derived progenitor cells and can take 4 to 6 months.[33]

Following unconditioned SCT for SCID, donor-derived stem cells have a selective advantage over genetically defective autologous HSCs in their capacity to differentiate to T cells. However, failure to obtain robust and durable engraftment of donor HSCs may occur if no conditioning is used. In such cases, after an initial period in which donor-derived committed lymphoid progenitor cells contained in the graft differentiate to T cells, lack of sustained seeding of HSC-derived progenitor cells in the thymus may cause reappearance of severe T-cell lymphopenia and affect the long-term durability and quality of immune reconstitution. For this reason, several centers prefer to perform haploidentical SCT with conditioning. A similar approach is typically followed when performing SCT from matched unrelated adult or cord blood.

While use of conditioning improves the rate of HSC engraftment, it is associated with short-term and long-term toxicity and an increased risk of GVHD, especially when myeloablative regimens are used. These risks may be attenuated by using reduced-intensity conditioning regimens. Finally, non-genotoxic approaches to conditioning with use of monoclonal antibodies (such as anti-CD117)[34] to target the autologous HSCs are currently being evaluated.

Survival and Long-Term Outcomes After Stem Cell Transplantation for Severe Combined Immune Deficiency

Survival after SCT for SCID has improved with time due to advances in early diagnosis and supportive care for infants with SCID.[35–37] Current figures indicate a 5-year survival that exceeds 90% in the case of SCT from matched sibling donors, and >80% in other cases. It has been demonstrated that age and clinical status at transplantation are the major determinants of survival.[36,38] In this regard, implementation of newborn screening may facilitate early identification of infants with SCID, prompting adoption of adequate measures to prevent infections and early referral to SCT. Rates of acute and chronic GVHD (aGvHD, cGvHD) are generally low and largely limited to recipients of SCT from donors other than HLA-matched siblings.

The durability and quality of immune reconstitution after SCT depend on multiple factors, including: (1) HLA matching between donor and recipient; (2) use of conditioning regimen; and, (3) the nature of the genetic defect causing SCID.[36] Survivors of SCT performed with a conditioning regimen tend to have higher counts of total and of naïve T-cells than those treated with SCT without conditioning.[36,38] Among recipients of SCT without conditioning, patients with RAG deficiency have an inferior long-term T cell reconstitution when compared to those with X-linked SCID or JAK3 deficiency or IL7R deficiency. This difference may be due to the fact that RAG deficiency is characterized by the presence of NK cells (which can mediate graft rejection and are absent in patients with X-linked SCID and JAK3 deficiency) and by a later block in intra-thymic T cell development, so that competition between donor-derived and autologous cells occurs during the initial stages of T-cell development. The nature of the genetic defect accounting for SCID may also determine whether use of conditioning regimen may be needed to obtain optimal reconstitution of humoral immunity. Forms of SCID where the genetic defect has no impact on B-cell development and function (such as IL7R deficiency) do not require conditioning, whereas chemotherapy-based preparative regimens that facilitate replacement of autologous HSCs with donor derived cells improve humoral immunity in patients with defects that affect B cell development (RAG deficiency). In the absence of conditioning, inadequate B-cell function (requiring immunoglobulin-replacement therapy) is often observed also in patients with γc and JAK3 deficiency, due to intrinsic defects in the host B-cell response to γc-dependent cytokines such as IL-4 and IL-21.[36] (See box on Therapeutic Approach to Severe Combined Immune Deficiency.)

Patients with poor T-cell reconstitution following SCT are at risk for viral and opportunistic infections; autoimmunity (especially cytopenias and hypothyroidism) has been reported in 10% to 20% of these patients, particularly in those with cGVHD.[39] Other long-term complications include nutritional problems, poor growth and development, and neurologic complications (mental retardation, motor dysfunction, sensorineural hearing deficits). Some of these complications are more common in certain subtypes, particularly growth in patients with Artemis-SCID and neurologic problems in patients with ADA deficiency.

Gene Therapy for Severe Combined Immune Deficiency

Gene therapy, in which the gene of interest is introduced into the patient's own cells, is an attractive therapeutic option for SCID, in particular for infants who do not have an HLA-identical related donor (see Chapter 104). Expression of the normal copy of the gene in $CD34^+$ stem cells confers a selective advantage to the gene-corrected cells during T-cell differentiation. Furthermore, there is no risk of GVHD. Gene therapy has been used successfully to correct SCID in patients with ADA deficiency and with X-linked SCID.[40]

Since the year 2000, more than 70 patients with ADA-deficient SCID have been treated with gene therapy worldwide. Initial studies have been conducted with transduction of the patients' $CD34^+$ cells

THERAPEUTIC APPROACH TO SEVERE COMBINED IMMUNE DEFICIENCY

- HSC transplantation is the mainstay of treatment. Optimal survival is achieved when the transplant is performed early in life. This is now possible with newborn screening.
- Transplantation for SCID can be performed without conditioning, due to the profound absence of T cells and inability to reject. Thus, the bone marrow of a fully HLA-matched sibling can be infused without manipulation and without giving any conditioning to the baby. GVHD prophylaxis is also not necessary. Haploidentical bone marrow from a parent can also be infused without conditioning but generally must be T-cell depleted either ex vivo or in vivo with agents such as cyclophosphamide.
- Such transplants without conditioning can result in T-cell reconstitution that lasts for decades. In the case of a matched sibling graft, initial T-cell reconstitution is rapid, generally within the first 1–3 months, due to proliferation of mature T cells. In the case of a haploidentical graft, mature T cells are removed and thus 4–6 months is required for HSC to develop and emerge from the thymus as mature T cells.
- Without conditioning, a small number of donor-derived long-lived HSCs engraft, and this may lead to lack of donor B-cell reconstitution and lack of humoral immunity. With conditioning, donor HSCs are more likely to engraft and give rise to donor B cells. Currently, matched unrelated donor transplants are performed with conditioning.
- Enzyme replacement may be used in patients with adenosine deaminase deficiency. Gene therapy has offered promising results; however, it is also associated with increased risk of developing leukemia due to insertional mutagenesis.

with gammaretroviral vectors expressing the ADA cDNA.[41–43] One such vector has received approval as orphan drug by the European Medical Agency. More recently, clinical trials of gene therapy for ADA deficiency have been conducted with use of lentiviral vectors, with great success.[44] Altogether, these experiences have been very successful, leading to sustained production of gene marked T, B and myeloid cells. The majority of patients have been able to stop ERT. Engraftment of gene-corrected stem cells has been facilitated by the use of a reduced-intensity chemotherapy regimen with low-dose busulfan. A single case of T-cell leukemia due to insertional mutagenesis of the retroviral vector has been reported.[45]

Twenty patients with X-linked SCID were treated by gene therapy using a gammaretroviral vector in Paris and London at the turn of the century, without chemotherapy conditioning.[46,47] Eighteen patients are alive, and 17 of them show normalization of T-cell count and function, with sustained thymic output, diversified T-cell repertoire, and ability to mount antigen-specific T-cell responses.[48,49] In a few cases, improvement of humoral immunity has also been observed. However, leukemic T-cell proliferation due to insertional mutagenesis was observed in six of these patients, with fatal outcome in one.[50,51] These serious events have led to the design of new vectors, including self-inactivating gammaretroviral[47] and more recently lentiviral vectors.[52,53] With these new vectors, successful immune reconstitution has been achieved in treated patients, including older patients who had shown declining immune function after previous SCT.[52] Improved B-cell reconstitution has been achieved in several patients after inclusion of conditioning with low-dose busulfan in the treatment protocol. Importantly, no cases of leukemia have been observed after gene therapy with self-inactivating viral vectors.

OTHER COMBINED IMMUNODEFICIENCIES

Defects of T-Cell Receptor Signaling

Several forms of combined immune deficiency are caused by genetic defects that affect the following molecules involved in TCR signaling.[54–58] In particular, the T lymphocyte-specific protein tyrosine kinase (Lck) associates with CD4 and CD8 molecules and mediates phosphorylation of CD3 chains upon TCR engagement. The Zeta-associated protein of 70 kDa (ZAP-70) tyrosine kinase phosphorylates the CD3 chains, thus promoting downstream TCR signaling. RHOH is an atypical Rho GTPase that participates in receptor-induced signaling in hematopoietic cells. The IL-2-inducible tyrosine kinase (ITK) is a member of the family of nonreceptor tyrosine kinases, and modulates the strength of the TCR-induced signal. The serine-threonine protein kinase 4 (STK4) protein induces the transcriptional coactivation of target genes involved in cell proliferation and survival and is involved in the control of cell death.

At variance with typical forms of SCID, genetic defects of TCR signaling are characterized by residual numbers and/or function of T cells, consistent with partially preserved thymic architecture and function. Since the thymus of these patients is not empty, the use of chemotherapy is required to facilitate engraftment and T-cell differentiation with donor-derived cells. The immunological phenotype of ZAP-70 deficiency in humans is characterized by a virtual lack of $CD8^+$ lymphocytes; the number of $CD4^+$ cells is preserved, but they are unable to proliferate in response to mitogens and antigens. In contrast, both $CD4^+$ and $CD8^+$ lymphocytes are absent in *Zap70*$^{-/-}$ mice.

Both Ras homolog family member H (RHOH) and STK4 deficiencies are characterized by a reduced number of naïve T cells, an increased proportion of effector memory T-cells (including $CD8^+$ cells with an “exhausted” $CD45RA^+CCR7^-$ phenotype), and defective lymphocyte proliferation. CD4 lymphopenia and low levels of CD4 and CD8 surface expression have been reported in LCK deficiency. Progressive CD4 lymphopenia is also commonly seen in patients with ITK deficiency.

Each of these forms of impaired TCR signaling are inherited as autosomal recessive traits. Clinically, patients with impaired T-cell signaling present with recurrent, often severe, infections. Cutaneous viral infections are especially common in patients with RHOH and STK4 deficiency. The clinical phenotype of ZAP-70 deficiency is often undistinguishable from SCID; in a few cases, hypomorphic *ZAP70* mutations have been associated with Omenn syndrome. Severe lung disease and a high risk of EBV-driven lymphoproliferation are a hallmark of ITK deficiency. Autoimmune manifestations have been observed in several patients with these disorders. Prevention of infections is based on antimicrobial prophylaxis and use of intravenous immunoglobulins; however, ultimate treatment requires SCT.

Coronin-1A Deficiency

Coronin-1A is involved in reorganization of the actin cytoskeleton that allows egress of thymocytes to the periphery. While complete deficiency of coronin-1A in humans is a cause of SCID, hypomorphic mutations have been associated with severe naive T-cell lymphopenia, oligoclonal expansion of activated T cells, and increased risk of EBV-driven lymphoproliferation.[59]

Human Leukocyte Antigen Class II Deficiency

Expression of HLA class II molecules on the surface of thymic epithelial cells (TECs) and dendritic cells is essential to promote positive selection of $CD4^+$ lymphocytes. HLA class II deficiency includes a group of autosomal recessive disorders in which mutations in transcription factors (*CIITA*, *RFXAP*, *RFX5*, and *RFXANK*) that regulate HLA class II gene expression result in profoundly reduced numbers of $CD4^+$ lymphocytes.[60] The clinical phenotype consists of recurrent infections since infancy. Treatment is based on antimicrobial prophylaxis, regular use of immunoglobulins, and SCT. Persistence of CD4 lymphopenia is often observed after SCT, because transplantation of HSCs does not correct defective expression of HLA class II molecules on the surface of TECs, causing defective positive selection of $CD4^+$ lymphocytes.

Human Leukocyte Antigen Class I Deficiency

Presentation of antigens in association with MHC class I molecules is important for thymic development of CD8$^+$ lymphocytes and for the development of antigen-specific cytotoxic T-cell responses. In addition, HLA class I molecules also modulate the function of NK cells that express several HLA class I-binding molecules. HLA class I molecules are assembled and loaded with peptides in the endoplasmic reticulum by transporter associated with antigen presentation (TAP) proteins (TAP1 and TAP2) and the TAP binding or Tapasin protein (TAPBP). Mutations of *TAP1*, *TAP2*, or *TAPBP* cause defective expression of HLA class I molecules, which is associated with a severe reduction in the number of circulating CD8$^+$ TCRαβ$^+$ lymphocytes.[60] NK cells expressing killer inhibitory receptors may not receive HLA class I-dependent inhibitory signals, and hence may mount cytotoxic responses to uninfected cells, causing inflammatory lesions in the lungs and in the skin. There is no definitive treatment for this disease, and management is based on supportive care.

CD40 Ligand and CD40 Deficiencies

CD40 ligand (CD40LG) is expressed by activated CD4$^+$ cells. Interaction of CD40LG-expressing CD4$^+$ cells with B lymphocytes that constitutively express CD40 delivers a signal for B-cell proliferation and class-switch recombination in the presence of appropriate cytokines (see Fig. 52.2). Furthermore, interaction between CD40LG-expressing CD4$^+$ lymphocytes and CD40$^+$ dendritic cells and macrophages promotes secretion of IL-12, and thus enables the development of Th1 responses against intracellular pathogens.

The *CD40LG* gene is located on the X chromosome (at Xq26). Males with *CD40LG* mutations suffer from a combined immunodeficiency characterized by recurrent infections, often caused by opportunistic pathogens.[61] *P. jiroveci* pneumonia classically occurs in the first year of life, but may occur at any age. *Cryptosporidium parvum* infection may cause chronic watery diarrhea and lead to sclerosing cholangitis. Chronic or intermittent neutropenia has been frequently observed. Patients with CD40LG deficiency are also uniquely prone to tumors of the liver and biliary tract.

Levels of serum IgG and IgA are markedly reduced or undetectable; IgM may be normal or increased, and for this reason the disease is also known as *X-linked hyper-IgM syndrome*. The number of memory B cells is also markedly reduced.

In vitro activation of T cells with phorbol myristate acetate and ionomycin fails to induce expression of CD40LG on the surface of CD4$^+$ cells, whereas other activation markers (e.g., CD69) are normally expressed.

The prognosis is severe. Death may occur early in life secondary to infections, or during late childhood and young adulthood due to severe liver disease and tumors.[62] Clinical management consists of continuous prophylaxis of *Pneumocystis* infection with TMP-SMZ, regular use of intravenous immunoglobulins, and hygiene measures to limit the risk of exposure to *Cryptosporidium*. SCT is the only definitive cure, with overall and disease-free survival of ~70% to 78% reported in Europe.[63] Preexisting pulmonary disease and *Cryptosporidium* infection are risk factors for less favorable outcomes.

CD40 deficiency is a very rare autosomal recessive disorder, whose clinical and immunological phenotype is indistinguishable from CD40LG deficiency (see Fig. 52.2).[64] The diagnosis is based on the lack of expression of CD40 on the surface of circulating B lymphocytes. Management is similar to that for CD40LG deficiency.

Defects of Nuclear Factor κB Signaling

The nuclear factor κ-B (NF-κB) signaling pathway is ubiquitous to all tissues and stages of development, playing critical roles in cell proliferation, oncogenesis, cell survival, and inflammatory responses. Several

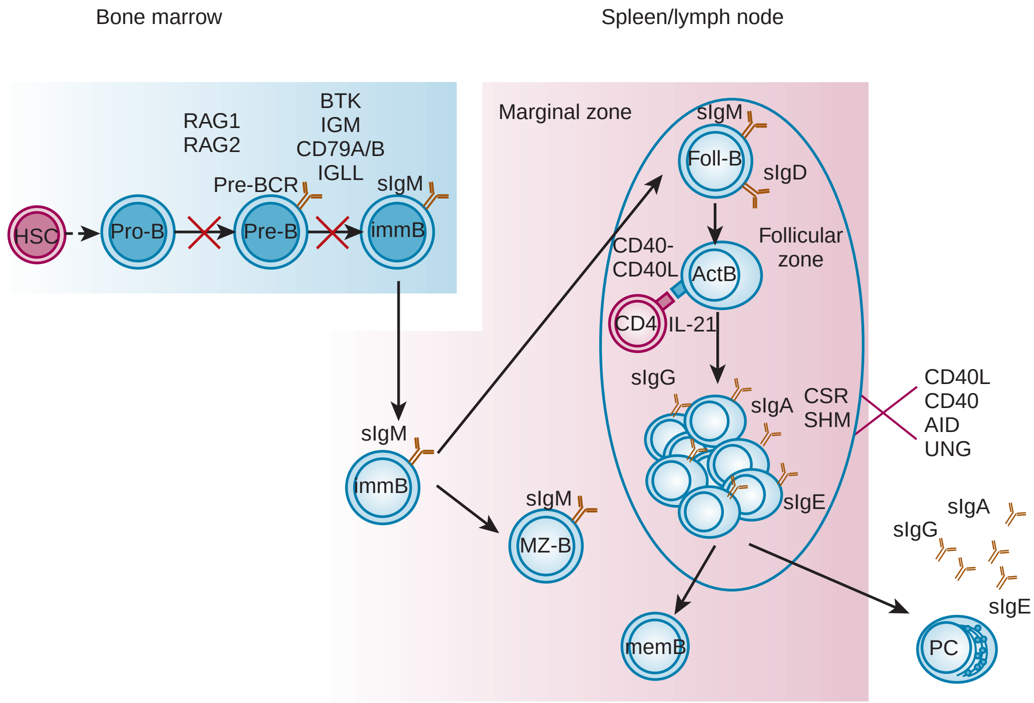

Figure 52.2 GENETIC DEFECTS ASSOCIATED WITH HYPOGAMMAGLOBULINEMIA. Schematic of B-cell development in bone marrow and secondary lymphoid organs, including migration of B cells into the follicular zone where they undergo activation, class-switch recombination (CSR), and somatic hypermutation (SHM). "X" denotes maturation steps at which the genes indicated are required, resulting in a block in differentiation at that stage when the gene is deficient. *ActB*, Activated B cell; *AID*, activation-induced cytidine deaminase; *BTK*, Bruton's tyrosine kinase; *Foll-B*, follicular B cell; *HSC*, hematopoietic stem cell; *IGLL*, immunoglobulin light-like chain; *IL-21*, interleukin-21; *immB*, immature B cell (also termed *transitional B cell*); *memB*, memory B cell; *MZ-B*, marginal zone B cell; *PC*, plasma cell; *Pre-B*, precursor B cell; *Pre-BCR*, pre–B-cell receptor; *Pro-B*, progenitor B cell; *RAG1*, recombination activating gene 1; *RAG2*, recombination-activating gene 2; *sIgA*, surface IgA; *sIgD*, surface IgD; *sIgG*, surface IgG; *sIgM*, surface immunoglobulin M; *UNG*, uracil-DNA glycosylase.

genetic defects affecting activation of NF-κB have been described that result in combined immune deficiency variably associated with extra-immune manifestations. Hypomorphic mutations in the *IKBKG* gene, which encodes for the NF-κB essential modulator (NEMO; also known as *IKK-γ*), the regulatory subunit of the IκB kinase complex, are inherited as an X-linked trait and represent the prototype of disorders of NF-κB signaling.[65] Complete lack of NEMO expression is embryonically lethal in males; females who are heterozygous for null NEMO mutations suffer from incontinentia pigmenti. Typically, males with NEMO deficiency present with ectodermal dysplasia and immunodeficiency (EDA-ID). The phenotypic manifestations of EDA-ID are largely restricted to epithelial tissues and the immune system, with sparse hair, shiny skin, lack of sweat glands and other appendages, and rare conical-shaped teeth. There is often frontal bossing and a characteristic facies. Typical infections are caused by bacteria, including sepsis and meningitis, especially *Streptococcus pneumoniae*, *Staphylococcus*, and *Haemophilus influenzae*; DNA viral infections such as CMV and herpes simplex virus (HSV); and atypical mycobacterial infection. Pneumocystis and other opportunistic infections may also occur. Inflammatory colitis is a frequent manifestation of immune dysregulation. Lymphedema and osteopetrosis have been reported in some patients. Occasionally, manifestations of ectodermal dysplasia may be modest or even absent, thus adding to phenotypic heterogeneity. Immunological abnormalities include variable defects in T-cell proliferation to mitogen and antigens, hypogammaglobulinemia with normal or high IgM, defective antibody production (especially against polysaccharides), and impairment of NK-cell cytotoxicity. Finally, monocytes from patients with NEMO deficiency fail to elaborate inflammatory cytokines such as tumor necrosis factor (TNF)α in response to stimulation by a variety of Toll-like receptor ligands. A similar clinical and immunological phenotype is observed in patients with autosomal dominant EDA-ID caused by gain-of-function (GOF) mutations of the *IKBA* gene. In these patients, the mutated IκB-α protein cannot be phosphorylated at residues that are critical for its degradation. This prevents release of the cytoplasmic components of NF-κB, which cannot translocate to the nucleus and mediate transcription of target genes.

Aside from supportive therapy with intravenous immunoglobulin replacement, antibiotic prophylaxis and treatment of infections, SCT for these disorders has been used with variable success. Because of the role of NF-κB signaling in nonhematopoietic tissues, certain manifestations of the disease, such as colitis, may not be uniformly ameliorated by SCT.[66]

Mutations of the *IKBKB* gene are responsible for an autosomal recessive disease, characterized by a SCID-like phenotype without ectodermal dystrophy.[67] Patients lack regulatory T cells and TCRγδ$^+$ T cells. The *MAP3K14* gene encodes for NIK, a component of the noncanonical NF-κB signaling pathway. Patients with NIK deficiency suffer from recurrent infections. Immunological abnormalities include reduced T-cell proliferation, hypogammaglobulinemia with reduced number of total and switched memory B cells, and NK deficiency.[68,69] Haploinsufficiency of *RELA*, encoding for the p65 subunit of NF-κB, is associated with impaired NF-κB activation and mucocutaneous ulcers.[70] Finally, autosomal recessive RelB deficiency is associated with normal numbers of T cells but reduced proliferation to mitogens and antigens, and restricted T cell repertoire. B cells are present in increased number; immunoglobulin levels are normal, but specific antibody production is impaired.

The CARD11–BCL10–MALT1 complex regulates NF-κB signaling. Deficiency of any of these proteins causes combined immune deficiency with increased susceptibility to infections. T-cell proliferation is impaired.[71] Defective antibody responses are observed in patients with BCL10 and CARD11 deficiency; the latter condition is also characterized by an increase in the proportion of transitional B cells.

FCHO1 Deficiency and Transferrin Receptor Deficiency

FCH and Mu Domain Containing Endocytic Adaptor 1 (FCHO1) is an adaptor protein involved in clathrin mediated endocytosis. Autosomal recessive FCHO1 deficiency is characterized by numerical and functional defects of T cells and impaired clathrin-mediated endocytosis, including defective transferrin and iron intake.[72,73] Patients suffer from severe infections early in life. An autosomal recessive missense mutation (Tyr20His) in the transferrin receptor (*TFRC*) gene causing impaired internalization of the transferrin receptor causes recurrent infections, neutropenia and thrombocytopenia associated with reduced T cell proliferation and low number of switched memory B cells.[74] Both FCHO1 and TFRC deficiency can be corrected by SCT.

Moesin Deficiency

Moesin is a member of family of proteins (also including ezrin and radixin) involved in reorganization of the actin cytoskeleton. X-linked moesin deficiency is a combined immunodeficiency disorder characterized by recurrent bacterial and viral infections (especially, varicella), molluscum contagiosum and eczema.[75] Immunological abnormalities include profound lymphopenia, fluctuating neutropenia and antibody deficiency.

Dedicator of Cytokinesis 2 Deficiency

The dedicator of cytokinesis (DOCK) proteins are atypical guanine exchange factors containing a phosphatidylinositol (3,4,5)-triphosphate (PIP3) binding domain and a Rho-family guanosine triphosphate phosphohydrolases (GTPase) binding domain with guanine exchange factor activity. DOCK2 is predominantly expressed in various hematopoietic cell lineages and is activated in response to engagement of the TCR, BCR, and chemokine receptors. DOCK2 activation allows formation of GTP Ras-related C3 botulinum toxin substrate 1 (GTP-Rac1), thereby promoting reorganization of the cellular cytoskeleton, and intracellular signaling. DOCK2 deficiency is an autosomal recessive combined immunodeficiency characterized by increased susceptibility to severe infections starting early in life.[76] Severe varicella has been reported in multiple patients. T-cell lymphopenia, with marked reduction of naïve T cells and impaired T-cell proliferation, defective antibody responses, reduced NK cell function, poor migration of T and B lymphocytes in response to chemokines, NKT-cell deficiency, and markedly reduced secretion of interferon-alpha (IFN-α) by plasmacytoid dendritic cells represent the major immunological abnormalities. Low TREC levels at birth have been reported in two patients. The prognosis is very poor, but definitive cure may be achieved with SCT. Use of systemic IFN-α may help in the treatment of severe viral infections.

Dedicator of Cytokinesis 8 Deficiency

DOCK8 deficiency is an autosomal recessive combined immunodeficiency characterized by severe and recurrent infections, particularly systemic and cutaneous viral infections (molluscum contagiosum, HSV-1 and HSV-2, human papillomavirus), allergic manifestations (early-onset eczema, food allergies) with elevated serum IgE, impaired humoral immunity (with frequent sino-pulmonary infections), and increased risk for squamous cell carcinoma and lymphoma.[77,78] Large intragenic deletions account for the majority of the mutations. Affected patients have low numbers of naive CD8 T cells, and accumulation of CD8 memory cells with an “exhausted phenotype”. A profound impairment in the generation of CD8$^+$ memory T cells in response to influenza or other viral infections has been reported. Humoral immunity is also compromised, with loss of germinal center B cells and defective immunoglobulin affinity maturation. The disease has a severe prognosis, with considerable mortality.[79] SCT represents the only definitive treatment. Use of systemic IFN-α may ameliorate manifestations of severe cutaneous viral infection.

Activated RAC2 Defect

RAC2 is a small GTPase. Heterozygous GOF mutations of *RAC2* cause a profound immunodeficiency with low number of T and B cells, poor antibody production and neutropenia, associated with increased susceptibility to infections and lymphoproliferation.[80–82]

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder, characterized by thrombocytopenia with small-sized platelets, eczema, and immunodeficiency.[79] Autoimmune manifestations are common, and there is an increased risk of developing hematologic malignancies (primarily non-Hodgkin lymphoma, often EBV-driven). The estimated incidence is 1 in 100,000 births. The defect is due to mutations in the *WAS* gene, which encodes an intracytoplasmic protein (WAS protein [WASp]) expressed in hematopoietic cells and involved in cytoskeleton reorganization and immune synapse formation.[83] Deficiency of WASp results in impaired T-cell activation, poor production of antibodies, particularly to carbohydrate antigens, defective NK cell function, impaired phagocytic cell migration, and defective antigen presentation, thus explaining the immunodeficiency associated with the disease.

The clinical phenotype may range from typical and severe WAS to isolated thrombocytopenia; milder phenotypes are often associated with residual expression of WASp.[84] Rarely, mutations occurring in the GTPase binding domain of the protein results in a hyperactive form of WASp, resulting in X-linked neutropenia and myelodysplasia without thrombocytopenia, eczema, or immunodeficiency.[85–87]

Boys with WAS typically present in infancy with bleeding manifestations that can range from petechiae and bruising, to severe gastrointestinal and intracranial hemorrhages.[79] Eczema can be mild to severe. Common infections in WAS patients include otitis, sinusitis, pneumonia, and cellulitis. Viral infections (especially from herpesviruses, including CMV, EBV, and HSV-1) and opportunistic infections, such as *P. jiroveci* pneumonia, are also frequent. Approximately 40% of patients with WAS develop autoimmunity, including autoimmune hemolytic anemia, autoimmune thrombocytopenia, thyroiditis, colitis, vasculitis, nephropathy, and arthritis.[88] In addition to thrombocytopenia, typical laboratory findings include inability to mount responses to polysaccharide antigens, low or absent isohemagglutinin titers, high IgE, and poor proliferation of T cells when stimulated with anti-CD3 antibody. Other immune findings are more variable, including progressive T cell lymphopenia with age, low IgM, and high IgA. Analysis of WASp expression and demonstration of *WAS* gene mutations confirm the diagnosis.

Supportive treatment for WAS consists of monitoring and treatment for bleeding, antimicrobial prophylaxis, immunoglobulin-replacement therapy, and treatment of eczema and autoimmune manifestations with immunosuppressive drugs. Splenectomy can be effective in many to correct thrombocytopenia, but leads to an increased risk of sepsis.

Allogeneic SCT (typically with myeloablative regimens) for WAS has become standard at many institutions, and may be indicated early in life, especially in patients with severe mutations that abrogate protein expression.[89,90]

SCT is usually associated with robust T-cell engraftment, whereas some patients develop mixed chimerism in the B and myeloid lineages, indicating differential requirement for normal WAS protein to promote lineage-specific development or survival.[89,90]

Survival after SCT for WAS is influenced by donor type and age at transplantation, but continuous improvement of outcome has been reported during the last decades. However, mixed chimerism may be associated with increased risk of autoimmunity, and low myeloid chimerism with persistence of thrombocytopenia.[89,90]

Gene therapy represents another treatment option for patients with WAS (see Chapter 104). In a first trial, 10 boys with WAS were treated with gene therapy by transduction of CD34$^+$-selected peripheral blood stem cells using a murine leukemia virus-based gammaretroviral vector after low-dose busulfan conditioning.[91] Immune reconstitution was attained in nine patients; however, seven of these developed leukemia due to insertional mutagenesis.[92] More recently, gene therapy for WAS has been performed using a self-inactivating lentiviral vector. Results show good immune reconstitution and improved safety (with no leukemic events reported); however, the platelet count, although increased, remains low in most patients.[93–95]

COMBINED IMMUNODEFICIENCIES WITH OSSEOUS DYSPLASIA

Cartilage hair hypoplasia (CHH) is an autosomal recessive disorder characterized by short-limbed dwarfism, hair abnormalities, increased risk of bone marrow dysplasia, malignancies and Hirschsprung disease, and a variable degree of immunodeficiency.[96] The majority of patients show susceptibility to bacterial and viral infections; however, some may present with SCID, Omenn syndrome, or selective deficiency of CD8$^+$ cells. The disease is more common among certain nationalities and communities (the Amish populations and the Finns), and is caused by mutations of the gene encoding for the untranslated RNA component of the ribonuclease mitochondrial RNA processing (*RMRP*) complex, which is involved in cleavage of ribosomal RNA, processing of mitochondrial RNA, and cell cycle control. Management of the immunologic problems in CHH depends on their severity. SCT may be indicated in cases with severe T lymphocyte defects.

Schimke immunoosseous dysplasia is an autosomal recessive disorder that also combines immunologic and skeletal abnormalities. These children have short stature, skeletal dysplasia, renal dysfunction and T-cell immunodeficiency caused by mutations in the *SMARCAL1* gene.[97]

Autosomal recessive EXTL3 deficiency due defects of heparan sulfate biosynthesis causes severe T-cell lymphopenia, short stature, cervical spine stenosis and neurodevelopmental delay.[98]

OTHER COMBINED IMMUNODEFICIENCIES

Mutations of ICOS, a molecule expressed by activated T cells, cause recurrent infections of the respiratory and gastrointestinal tracts and autoimmunity.[99]

Heterozygous dominant-negative mutations of the *IKZF1* gene, encoding for the transcription factor IKAROS, cause a combined immunodeficiency with recurrent infections (including a high rate of *P. jiroveci* pneumonia). Generation of memory T and B cells is severely impaired.[100]

Hepatic venoocclusive disease with immunodeficiency is an autosomal recessive condition caused by mutations of the *SP110* gene.[101] In addition to liver disease, patients are highly prone to infections that are often sustained by opportunistic pathogens (CMV, *Candida*, *P. jiroveci*). Cerebrospinal leukodystrophy has been observed in several cases. The disease is rapidly fatal, unless treated by SCT.

Autosomal recessive combined immune deficiency with intestinal atresia is caused by mutations in the *TTC7A* gene, which encodes for a protein involved in maintaining cell polarity in epithelial cells.[102,103] Variable, but often severe, lymphopenia and panhypogammaglobulinemia are typical immunological abnormalities. The prognosis is generally severe and is determined by the severity of the gastrointestinal involvement and of immune deficiency. Small-bowel transplantation is often necessary. In patients with profound immune deficiency SCT may be required and does not in general improve the intestinal manifestations[104]; however, limited data are available on long-term outcome.

The cytidine triphosphate synthase 1 (CTPS1) protein is essential for lymphocyte proliferation. Patients with CTPS1 deficiency have a high risk of recurrent and chronic infections (especially those due to herpesviruses), and of EBV-related lymphoma.[105]

A very high risk of EBV-induced lymphoproliferative disease (see Chapter 87) is also observed in patients with CD27 and with CD70 deficiency. These patients lack memory B cells and often develop hypogammaglobulinemia after EBV infection.[106–108]

EBV-associated lymphoma (see Chapter 87) is a common manifestation in patients with magnesium transporter type 1 (MAGT1) deficiency.[109] This condition is inherited as an X-linked trait. The number of naive $CD4^+$ T cells is reduced, and expression of NKG2D, an important activating molecule, on the surface of $CD8^+$ cytotoxic T cells and NK lymphocytes, is markedly decreased. SCT can correct the disease.[110]

CD137 (4-1BB) is a costimulatory molecule, whose deficiency causes an increased risk of EBV-lymphoproliferative disease, chronic active EBV infection and B-cell lymphoma.[111]

IL-21 and IL-21R deficiencies are inherited as autosomal recessive traits.[112] Gastrointestinal manifestations with colitis and *Cryptosporidium*-associated cholangitis have been reported. A single patient with Kaposi sarcoma and OX40 deficiency has been reported.[113]

Autosomal recessive deficiency of phosphoglucomutase 3 (PGM3) is a disorder of glycosylation characterized by severe atopy, skeletal problems, cutaneous viral infections, respiratory tract infections and increased risk of lymphoma. Immunological abnormalities include impaired T-cell activation, elevated serum IgE and defective antibody production.[114,115]

DISORDERS WITH T-CELL-MEDIATED IMMUNE DYSREGULATION

Along with generation of a diversified repertoire of T and B lymphocytes, purging of self-reactive cells is essential to maintain immune homeostasis and prevent autoimmune diseases. Some forms of primary immunodeficiency manifest with immune dysregulation due to genetic defects of central or peripheral T-cell tolerance.

Autoimmune Polyendocrinopathy Candidiasis Ectodermal Dystrophy Syndrome

Also known as *autoimmune polyglandular syndrome type 1* (APS1), autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) is an autosomal recessive disorder characterized by autoimmune endocrine manifestations (hypoparathyroidism, Addison disease), candidiasis, and nail dystrophy.[116,117] The disease is caused by mutations of the autoimmune regulator (*AIRE*) gene,[118,119] which encodes for a transcription factor expressed by medullary TECs (mTECs) where it regulates expression of tissue specific antigens that are presented to nascent T cells, thereby promoting clonal deletion of self-reactive T lymphocytes, or their conversion to natural regulatory T cells (nTreg cells).

In patients with APECED, mucocutaneous candidiasis usually develops first (in infancy or early childhood), followed by autoimmune hypoparathyroidism with hypocalcemia and adrenal failure. Around 15% to 20% of patients may develop insulin-dependent diabetes. Gastrointestinal and pulmonary involvement, reflecting autoimmune damage, are frequently observed. Autoimmune hepatitis and ovarian failure are also common. Candidiasis may reflect elevated levels of antibodies to IL-17 and IL-22, which play an important role in the defense against *Candida* spp.

Management of patients with APECED is based on regular follow-up and searching for autoantibodies, which should be repeated every 6 months. Hormone-replacement therapy is indicated for the endocrinopathies. Aggressive management and prevention of candidiasis is important to avoid persistent or recurrent infections that may favor development of squamous cell carcinoma.

Immune Dysregulation Polyendocrinopathy Enteropathy X-Linked Syndrome

Immune dysregulation polyendocrinopathy enteropathy X-linked (IPEX) is an X-linked disorder of systemic autoimmunity.[120] Males with IPEX syndrome present early in life with skin rash, intractable watery diarrhea, insulin-dependent diabetes mellitus, lymphadenopathy, splenomegaly, and failure to thrive. Other autoimmune manifestations include thyroid disease, nephropathy, cytopenias, and vasculitis. In addition, patients with IPEX show elevated levels of IgE.

IPEX is caused by mutations of the *FOXP3* gene, which encodes for a transcription factor that plays a critical role in the development and function of regulatory T (Treg) lymphocytes.[121] These cells have suppressive functions; they have a distinctive phenotype ($CD4^+$ $CD25^{hi}$ $FOXP3^+$) and normally represent 5% to 15% of $CD4^+$ circulating lymphocytes.

IPEX has a poor prognosis. Death often occurs within the first few years of life due to severe malabsorption, failure to thrive, metabolic derangement, or because of severe infections secondary to immune suppression. Use of immunosuppressive drugs (steroids, sirolimus, tacrolimus, rituximab) is necessary to treat the disease. However, the only definitive treatment is allogeneic SCT.[122]

CD25 and STAT5B Deficiencies

IL-2 plays an important role in T lymphocyte proliferation and in immune homeostasis. Upon binding to the high-affinity IL-2 receptor, IL-2 promotes phosphorylation and nuclear translocation of the transcription factor signal transducer and activator of transcription (STAT)5, which drives expression of IL-2 target genes, including *FOXP3*. Autosomal recessive mutations of the *IL2RA* (*CD25*) gene, which encodes for the α chain of the IL-2 receptor, cause a disease that is associated with IPEX-like manifestations (lymphadenopathy, hepatosplenomegaly, autoimmune cytopenias, inflammatory bowel disease) and increased susceptibility to severe viral infections.[123] A similar phenotype may also be caused by mutations of the *IL2RB* gene, encoding for the IL-2Rβ chain.[124] HCT represents the only definitive treatment.

Autosomal recessive mutations of the *STAT5B* gene cause a syndrome characterized by autoimmunity (especially cytopenias and autoimmune hepatitis), eczema, severe and/or recurrent infections, lymphocytic interstitial pneumonia, and growth hormone (GH)-insensitive dwarfism.[125] The latter reflects the critical role played by STAT5 in the cellular response to GH. Affected patients have a low number of circulating T and NK lymphocytes and Treg cells, and in vitro proliferative responses to mitogens are reduced. In contrast, IgG levels are often elevated. Aggressive treatment of infections, use of immunosuppressive drugs to treat autoimmune manifestations, and regular monitoring of pulmonary function are the mainstay of treatment.

Cytotoxic T Lymphocyte Antigen 4 Deficiency

Cytotoxic T lymphocyte antigen 4 (CTLA4) is a surface molecule expressed by conventional and regulatory T cells. It competes with CD28 for binding to CD80/CD86 molecules expressed by antigen-presenting cells. However, in contrast to CD28, CTLA4 delivers a suppressive signal that limits T-cell activation. Heterozygous loss-of-function mutations of CTLA4 cause a condition characterized by lymphoid infiltrates in the lung, gastrointestinal tract, and the brain (simulating lymphoma), autoimmune cytopenias, hypogammaglobulinemia, lymphopenia, accumulation of activated T cells, and decreased Treg-cell function. The disease is inherited as an autosomal dominant trait with incomplete penetrance. Treatment is based on use of CTLA4-Ig (abatacept) and sirolimus. SCT may be considered in severe cases.

Lipopolysaccharide Responsive Beige-Like Anchor Protein Deficiency

Deficiency of the lipopolysaccharide responsive beige-like anchor protein (LRBA) is inherited as an autosomal recessive trait and causes a combined immunodeficiency with prominent immune dysregulation affecting mostly the gastrointestinal tract (with severe chronic diarrhea and failure to thrive) and the lungs.[126–128] Autoimmune cytopenias are also common. Typical immunological abnormalities include hypogammaglobulinemia and a variable degree of lymphopenia, with increased proportion of activated T cells. The disease shares some clinical and immunologic manifestation similarities with CTLA4 deficiency.[129] Indeed, LRBA binds to CTLA4 and allows endosomal trafficking of the latter to the cell membrane. In the absence of LRBA, CTLA4 is targeted to the lysosomal compartment where it is degraded. Consistent with this, Treg cells from patients with LRBA deficiency have low levels of expression of CTLA4 and FOXP3, and the actual number and function of Treg lymphocytes are impaired. Treatment with CTLA4-Ig (alone or in combination with sirolimus) may be beneficial.

DEF6 deficiency

Differentially expressed in FDCP 6 homolog (DEF6) is a guanine nucleotide exchange factor involved in TCR signaling. DEF6 deficiency affects availability of CTLA-4 at the cell surface and Treg function.[130] Clinical manifestations include recurrent infections, enteropathy, cardiomyopathy and lymphoproliferation with hepatosplenomegaly.

Defects of Calcium Flux

T lymphocyte activation and homeostasis depend on calcium mobilization. In particular, TCR-induced activation results in release of Ca^{2+} from the endoplasmic reticulum stores, followed by Ca^{2+} entry through the Ca^{2+} release-activated channels (CRAC) located in the cell membrane. Mutations of *STIM1* (which encodes for a sensor of endoplasmic reticulum calcium stores) and of *ORAI1* (which encodes for CRAC) cause severe immunodeficiency in which T-lymphocyte generation in the thymus is not affected, but peripheral T cells are functionally impaired.[131,132] Autoimmunity and nonprogressive myopathy are distinguishing features of these disorders.

Autoimmune Lymphoproliferative Syndrome

Interaction between FAS (CD95) on activated T and B lymphocytes, and Fas ligand (FASLG) on activated T cells triggers the extrinsic pathway to activation of the caspase cascade, culminating in apoptosis. In addition, cellular stress (including cytokine deprivation) may activate the intrinsic pathway of apoptosis, leading to disruption of mitochondrial membrane permeability, release of cytochrome c, activation of caspase 9 and apoptosis. Defects of FAS- or mitochondrial-dependent apoptosis are responsible for autoimmune lymphoproliferative syndrome (ALPS), characterized by early-onset, chronic (>6 months), nonmalignant lymphoproliferation, autoimmunity, and increased risk of lymphoma.[133]

The majority of patients with ALPS carry heterozygous dominant-negative mutations in the *FAS* (*CD95*, *TNFRSF6*) gene (ALPS-FAS).[134,135] Somatic mutations of the *FAS* gene are the second most common cause of the disease (ALPS-sFAS).[136] More rarely, ALPS is caused by mutations of the *FASLG* gene (ALPS-FASLG), of caspase 8, caspase 10, Fas-associated death domain (FADD) protein, or by somatic activating mutations of N-RAS or K-RAS.[137] Finally, autosomal recessive deficiency of protein kinase C (PRKCD), which plays an important role in regulating cell survival and apoptosis, also causes an ALPS-like disease with B-cell lymphoproliferative disease.[138,139]

Lymphoproliferation, manifesting as lymphadenopathy, splenomegaly, or hepatomegaly, is the most common clinical manifestation, with a trend toward progressive remission in adulthood. More than 70% of ALPS patients develop autoimmune disease—most commonly immune cytopenias, less frequently organ-specific autoimmunity. There is an increased risk of malignancies, especially EBV-associated non-Hodgkin lymphoma. Patients with PRKCD deficiency often present with SLE-like manifestations, with nephropathy and antiphospholipid antibody syndrome.[138,139]

An immunologic signature of ALPS is the increased number of DN circulating T lymphocytes that express the αβ form of the TCR, but do not express CD4 or CD8 molecules.[133] There is defective in vitro apoptosis of lymphocytes through the FAS-mediated or intrinsic pathway (depending on the genetic variant). Elevated levels of soluble FAS ligand, vitamin B_{12}, and IL-10, hypergammaglobulinemia, and anti-phospholipid antibodies are often present in patients with ALPS-FAS. By contrast, patients with PRKCD deficiency have low levels of IgG and an increased proportion of $CD5^+$ B cells. Patients with caspase 8 deficiency, FADD deficiency, and PRKCD deficiency have recurrent infections. The number of DN T cells may be normal in patients with *NRAS* or *KRAS* mutations.

Treatment is based on immunosuppression (with steroids, rituximab, mycophenolate mofetil, or sirolimus) and surveillance for lymphoma.[140] Splenectomy may improve cytopenias; however, relapse of autoimmunity has been observed in 50% of the splenectomized patients. Furthermore, severe, invasive bacterial infections have been reported in 30% of splenectomized patients, and the mortality rate for invasive bacterial infection after splenectomy is as high as 13.3%.

Other Conditions With Immune Dysregulation

***STAT1* GOF** mutations cause a variable clinical phenotype ranging from chronic mucocutaneous candidiasis to increased occurrence of viral, fungal, and bacterial infections, to autoimmunity.[141]

GOF mutations of *STAT3* cause increased STAT3 signaling and enhanced Th17 differentiation, with lymphoproliferation and solid-organ autoimmunity. The number of Treg cells is reduced.[142–144]

GOF mutations of *JAK1* cause an autosomal dominant condition with hypereosinophilia, hepatosplenomegaly, eosinophilic enteritis, poor growth and viral infections.[145]

Deficiency of ITCH, an E3 ubiquitin ligase that regulates activation of phospholipase Cγ1 (PLCγ1), causes multiple autoimmune manifestations (enteropathy, thyroiditis, type 1 diabetes, hepatitis), interstitial lung disease, dysmorphic features, and developmental delay.[146]

Defects of IL-10 and IL-10R are responsible for very early onset inflammatory bowel disease.[147]

Mutations of the tripeptidyl-peptidase II (*TPP2*) gene cause severe autoimmune hemolytic anemia, variable lymphoproliferation, and recurrent infections. Accelerated senescence of lymphoid cells and hypergammaglobulinemia are observed.[148]

DEFECTS OF CELL-MEDIATED CYTOTOXICITY

Mechanisms of immune defense against viral infections are largely dependent on responses mediated by $CD8^+$ cytotoxic T lymphocytes (CTLs) and NK lymphocytes. Multimers of perforin, a protein contained in cytolytic granules, form pores through which CTL and NK cells release cytotoxic proteins (granzyme B, granulolysin) into virus-infected target cells, causing activation of caspases and apoptosis. In resting CTLs and NK lymphocytes, cytotoxic proteins are contained in endosomal secretory lytic granules. Following interaction of CTLs or NK cells with the target cell, vesicles containing lytic granules are transported and dock and fuse with the cell membrane, permitting release of cytotoxic proteins into the target cells.

Hemophagocytic Lymphohistiocytosis

Defects in the intracellular transport and release of cytolytic granules are responsible for various forms of familial HLH, including deficiency of Munc13-4 (required to prime vesicles), syntaxin 11 and Munc18-2 (both of which promote vesicle fusion with the cell membrane), RHOG and perforin.[149] In these disorders, infections (mostly caused by viruses) trigger an uncontrolled immune response mediated by CD8$^+$ T lymphocytes and NK cells that secrete large amounts of IFN-γ, which activates macrophages. Fever, liver, and splenic enlargement, lymphadenopathy, profound cytopenias, hypoalbuminemia, coagulopathy, high levels of ferritin and triglycerides, and immune activation (with increased levels of soluble CD25) characterize these acute episodes, which may lead to multiple-organ failure and death. The diagnosis of these familial forms of HLH is facilitated by flow cytometric analysis of surface expression of CD107a (a protein normally contained in endosomal vesicles) upon in vitro activation of cytotoxic T cells and NK cells. Defective expression of CD107a is observed in patients with Munc13-4, Munc18-2, and syntaxin 11 deficiencies. By contrast, this test is normal in patients with perforin deficiency, in which reduced or absent expression of perforin can be easily demonstrated by flow cytometry.

Zinc finger NFX1-type containing 1 (ZNFX1) is an interferon-stimulated double-strand RNA sensor. Autosomal recessive **ZNFX1 deficiency** causes increased susceptibility to viral infections, HLH-like manifestations, early-onset seizures, as well as renal and lung disease.[150,151]

Human Leukocyte Antigen Associated With Pigmentary Dilution Disorders

Typical features of HLH are also observed in some pigmentary dilution disorders.[149] In particular, Chediak-Higashi syndrome (CHS) (see Chapter 51) is an autosomal recessive disease due to mutations of the *LYST* gene, which encodes for a protein involved in the sorting of proteins to secretory endosomes. This defect affects not only cytotoxic lymphocytes (accounting for FHL-like clinical features), but also melanocytes (that are unable to transfer melanin to keratinocytes and other epithelial cells) and peripheral neurons. Clinical features of CHS include partial albinism (with silvery hair), progressive peripheral neuropathy, recurrent bacterial infections, and a mild bleeding tendency. Neutropenia is often present and may cause bacterial infections. Giant lysosomes can be identified in circulating leukocytes.

Griscelli syndrome type 2 (GS2) is caused by mutations of the *RAB27A* gene, which encodes for a protein involved in docking of secretory granules of cytotoxic lymphocytes and melanocytes to the cell membrane. Accordingly, patients with GS2 present with HLH and hypopigmentation. The diagnosis is facilitated by the demonstration of large clumps of pigment distributed irregularly along the hair shaft, and by reduced expression of CD107a on the surface of CD8$^+$ and NK lymphocytes upon in vitro activation.

Hermansky-Pudlak syndrome type 2 (HPS2) and HPS10 are autosomal recessive disorders caused by mutations of the *AP3B1* and the *AP3D* genes, which encodes for the β and the δ components of the AP-3 complex, respectively, involved in sorting of transmembrane proteins to secretory lysosomes. Both disorders are characterized by partial albinism, nystagmus, recurrent bacterial and viral infections, neutropenia and defective cytotoxic activity account for increased risk of HLH. In addition, HPS2 patients have tendency to bleeding due to platelet dysfunction (with absence of dense granules and reduced platelet aggregation), whereas patients with HPS10 have hearing loss and developmental delay.

Irrespective of the nature of the genetic defect, HLH therapy is based on the prompt and aggressive treatment of underlying infections and immunosuppression to curtail macrophage activation. Administration of humanized anti-IFN-γ monoclonal antibodies may block continuous activation of the immune system and induce remission.[152] Ultimately, definitive treatment is based on allogeneic SCT from a matched related or unrelated donor; while survival is better with reduced-intensity conditioning, a high incidence of graft failure favors the use of moderate intensity regimens.[153] Mixed chimerism is sufficient to correct the immunologic abnormalities. (See box on Diagnostic and Therapeutic Approach to Cytotoxicity Defects.)

X-Linked Lymphoproliferative Disease

In normal individuals, primary infection with EBV causes infectious mononucleosis, a self-limiting disease. EBV establishes latency in B lymphocytes, salivary glands, and some epithelial cells, and is maintained under control by CD8$^+$ CTLs, and NK lymphocytes. Males with X-linked lymphoproliferative disease type 1 (XLP1) are uniquely susceptible to life-threatening complications of EBV infections.[154] XLP1 is caused by mutations of the *SH2D1A* gene, which encodes for a small adaptor molecule, SLAM-associated protein (SAP).[155–157] In the absence of SAP, cytotoxic responses to EBV-infected cells are markedly reduced. Persistence of EBV triggers continuous activation of CD8$^+$ CTLs that release high amounts of IFN-γ, ultimately resulting in a macrophage activation syndrome. In addition to HLH, patients with XLP1 are also at high risk of B-cell lymphoma. SAP is also important for the function of follicular helper T cells (T_{FH}), which promote maturation of antibody responses. Consistent with this, XLP1 males often develop hypogammaglobulinemia with a lack of memory B lymphocytes. Finally, XLP1 is also associated with impaired development of NK T (NKT) lymphocytes. Flow cytometric analysis of SAP expression and mutation analysis at the *SH2D1A* locus confirms the diagnosis.

A minority of patients with XLP carry defects in another gene (*BIRC4*) that encodes for the X-linked inhibitor of apoptosis (XIAP).[158] Consistent with this, lymphocytes from patients with this disease (XLP2) show increased susceptibility to activation-induced apoptosis. Compared to XLP1, patients with XLP2 have a higher incidence of HLH (with or without EBV infection), but do have an increased risk of lymphoma. Severe inflammatory bowel disease has been reported in several patients. Hypogammaglobulinemia is often present. Flow cytometric analysis of XIAP expression and mutation analysis at the *BIRC4* locus are used to confirm the diagnosis.

DIAGNOSTIC AND THERAPEUTIC APPROACH TO CYTOTOXICITY DEFECTS

- Primary immunodeficiency with defects of cell-mediated cytotoxicity include a heterogeneous group of disorders characterized by increased susceptibility to severe viral infections.
- Typical clinical features include high fever, liver and splenic enlargement, lymphadenopathy, coagulation defects, abnormalities of liver function, and cytopenias after viral infections.
- Two major groups of cell-mediated cytotoxicity defects include familial forms of HLH (fHLH) and X-linked lymphoproliferative disease. In the former, diagnosis is based on demonstration of abnormal cytotoxic function of T and NK lymphocytes. Defective expression of CD107a on activated lymphocytes or reduced expression of perforin may help define the nature of the underlying disorder causing fHLH.
- Prompt recognition and treatment of the underlying infection is essential. Immunosuppression is also required to block exaggerated inflammatory responses. However, the only curative approach to defects of cell-mediated cytotoxicity is represented by SCT. Mixed chimerism is sufficient to allow immune reconstitution. This goal can be achieved with reduced intensity conditioning, with a lower risk of treatment-related toxicity but also a risk of graft failure.

Both XLP1 and XLP2 are life-threatening disorders. Administration of immunoglobulins may be beneficial; however, the only curative approach is SCT.

DEFECTS OF B-CELL DEVELOPMENT AND FUNCTION

The prior section covered defects that predominantly affect T lymphocyte development and/or function. This section covers primary immunodeficiencies in which abnormalities of B-cell development and/or function predominate (see Figs. 52.2 and 52.3).

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA), also known as *Bruton's agammaglobulinemia*, is the most common monogenic cause of failure of B-cell development. Males with XLA lack circulating B cells, caused by mutations of the Bruton's tyrosine kinase or *BTK* gene, which encodes for a tyrosine kinase involved in signaling through various receptors, including the pre–B-cell receptor (pre-BCR) and the BCR.[159,160] Impaired signaling through the pre-BCR causes a severe, but incomplete, block at the pre–B-cell stage in the bone marrow (see Fig. 52.2).

Clinical manifestations of XLA include recurrent sinopulmonary infections (pneumonia, bronchitis, sinusitis, otitis), particularly with encapsulated organisms such as pneumococcus and *Haemophilus influenza*, bacterial skin infections (cellulitis, impetigo, pyoderma gangrenosum, perirectal abscess), and sepsis with *Pseudomonas* or *Staphylococcus*.[161] Symptoms typically begin after 3 to 6 months of age when maternally derived antibodies disappear. The proportion of circulating B cells is markedly reduced (typically 0.05% to 0.3% of lymphocytes) and there is profound deficiency of all immunoglobulin isotypes. Neutropenia, secondary to severe infections, is observed in approximately 10% to 25% of patients; typically, it resolves with antibiotics and immunoglobulin-replacement therapy.

In addition to bacterial infections, patients with XLA are uniquely susceptible to enteroviral infections (including chronic meningoencephalitis) caused by poliovirus, coxsackie virus, and others. However, such complications have become rare after the introduction of optimal doses of immunoglobulin-replacement therapy. Patients with XLA are also at higher risk of infections caused by *Mycoplasma* and *Ureaplasma* species, which affect the joints, prostate, or lungs; and *Giardia lamblia*, causing protracted diarrhea and malabsorption. An increased incidence of lymphoma, colorectal cancer, and gastric adenocarcinoma has been reported in XLA.

Therapy is based on life-long regular administration of immunoglobulins intravenously or subcutaneously, and on prompt and aggressive treatment of infections. With this regimen, survival approaches that of the general population. Antibiotic prophylaxis may be beneficial, but its role has not been firmly established. Patients on immunoglobulin-replacement therapy should be monitored for side effects and adverse reactions, and for liver and renal function.

Autosomal Recessive Agammaglobulinemia

While the majority of agammaglobulinemia cases are caused by the X-linked form, about 15% of cases are presumed to be autosomal recessive (see Fig. 52.2).[161,162] Mutations of the immunoglobulin μ heavy chain gene (*IGHM*) are the second most common cause of agammaglobulinemia. Other cases are caused by defects in other components of the pre-BCR/BCR complex including the signaling moieties Igα (CD79A) and Igβ (CD79B), and λ5 (IGLL1), the surrogate light chain that pairs with Vpre-B, and the scaffold protein BLNK, which brings BTK into the signaling complex. Finally, congenital agammaglobulinemia may also be caused by mutations of the *PIK3CD* and *PIK3R1* genes, causing complete loss of the p110α and p85α subunits, respectively, of phosphatidylinositol 3-kinase (PI3K), and to heterozygous, dominant-negative mutations of the *TCF3* gene encoding for the transcription factor E47.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is the most common primary immunodeficiency severe enough to require treatment, with a prevalence estimated to be 1 in 25,000 to 1 in 30,000 Caucasians, and accounting for approximately 10% to 20% of humoral immunodeficiencies. A growing number of genetic defects have been found to be associated with a CVID phenotype, but most cases remain genetically undefined.[163] Mutations in transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI) can also be found in asymptomatic individuals,[164,165] and more likely represents a predisposition to CVIDs than primary cause.

Mutations in CD19, CD81, and CD21, which are all components of the B-cell coreceptor, have been reported in few individuals. These defects do not affect B-cell development but impair signaling, causing hypogammaglobulinemia, low number of switched memory B cells, and poor antibody response to T-independent antigens. In addition to recurrent infections, patients with CD19 and CD81 deficiency may also develop glomerulonephritis.

CD20 is a surface molecule involved in B-cell development and plasma cell differentiation. Autosomal recessive CD20 deficiency is characterized by recurrent infections, low serum IgG, with normal or elevated IgA and/or IgM.

BAFF-R deficiency is very rare. It has a variable clinical presentation, with CVID-like features or even absence of symptoms. Laboratory findings include hypogammaglobulinemia, low numbers of circulating B cells, a defective proportion of memory B cells, and normal antibody response to T-dependent antigen but a defective response to carbohydrate antigens.

A variable clinical phenotype has been also reported in patients with haploinsufficiency of the p50 subunit of NF-κB (encoded by the *NFKB1* gene), causing defective signaling through the canonical NF-κB signaling pathway. In addition to recurrent infections and progressive lung disease, patients often present with autoimmunity (hemolytic anemia, thyroiditis, alopecia) and lymphadenopathy. However, genotypically affected individuals may also remain asymptomatic even through adulthood. Heterozygous mutations of the *NFKB2* gene (affecting mostly the noncanonical NF-κB signaling pathway) cause recurrent infections (especially due to HSV, varicella-zoster virus [VZV], and *Giardia*), central adrenal insufficiency, hypopituitarism, alopecia, trachyonychia, and growth deficiency. Hypogammaglobulinemia, a low number of memory B cells, Treg lymphocytes, T follicular helper (Tfh) cells, and NK lymphocytes have been demonstrated.

Haploinsufficiency of the *IKZF1* gene, causes recurrent infections and autoimmunity, associated with progressive B-cell lymphopenia and hypogammaglobulinemia. These patients are at significantly increased risk of acute lymphoblastic leukemia.

Autosomal recessive RAC2 deficiency causes recurrent infections, post-streptococcal glomerulonephritis and urticaria, along with hypogammaglobulinemia and poor antibody production.

Diagnostic criteria for CVIDs include the presence of hypogammaglobulinemia (<2 standard deviations below the mean for age of IgG, IgA, and/or IgM) and the lack of specific antibody responses in individuals with onset of symptoms >2 years of age, for whom other causes of humoral immunodeficiency have been ruled out.[166] The number of circulating B cells detected is variable. Specific antibody responses should be assessed for more than one antigen.

Consistent with the antibody deficiency, CVID patients have recurrent bacterial infections of the respiratory tract, sepsis with encapsulated organisms, and infections from *Ureaplasma uraelyticum*, *Giardia* species and enteroviruses. However, variable derangement of T-cell numbers and function often results in noninfectious manifestations, including autoimmunity, lymphoid infiltration or proliferation, and malignancy. In one survey only 26% of CVID patients had infections as the only manifestation of disease.[167] Autoimmune cytopenias are quite common (~12%) and may be the presenting feature. Other autoimmune complications include rheumatoid arthritis, systemic lupus erythematosus, hypothyroidism, vitiligo, psoriasis, diabetes, and autoimmune gastritis with pernicious anemia. Polyclonal lymphocytic granulomatous infiltrates are common and may involve the lungs, liver, or gut (causing enteropathy that is resistant to gluten withdrawal). Finally, both lymphoid (non-Hodgkin lymphoma, chronic lymphocytic leukemia) and nonlymphoid (gastric cancer) malignancies, as well as nonmalignant lymphoproliferation,[168] are more frequent in CVID, although the gastric cancers may be related to *Helicobacter pylori* infection.

Replacement of immunoglobulins and treatment and prevention of infection remains the mainstay of management of CVID.[162] Immunosuppression may be needed for inflammatory and autoimmune manifestations. Disease manifestations such as autoimmunity, polyclonal lymphocytic infiltrative disease, enteropathy, and malignancy have differential and increasing impact on survival (relative risk of death 2.5, 3.0, 4.0, and 5.5, respectively), while patients with solely infectious manifestations have equivalent survival to the general population. Treatment with HCT has been performed with limited success, and often in the context of consolidative treatment for lymphoproliferation. (See box on Diagnostic and Therapeutic Approach to Defects in Humoral Immunity.)

B-CELL–INTRINSIC DEFECTS OF CLASS-SWITCH RECOMBINATION

Maturation of the antibody response is marked by class-switch recombination (CSR) and by somatic hypermutation (SHM). With CSR, the μ heavy chain is replaced by other Ig heavy chains. With SHM, mutations are introduced in the Ig V region, allowing affinity maturation. Following CD40LG–CD40 interaction and activation of the NF-κB signaling pathway, expression of activation-induced cytidine deaminase (AID) and of uracil-DNA glycosylase (UNG) occurs in germinal center B lymphocytes (see Fig. 52.3). AID acts on the DNA of Ig heavy chain switch regions and converts cytidine to uridine, which is recognized and removed by UNG. The abasic sites are cleaved by a DNA endonuclease. DNA repair then brings together two different switch regions, allowing CSR.

Mutations in AID and UNG are inherited as autosomal recessive traits.[169] Patients suffer from recurrent bacterial infections. Autoimmune manifestations have been observed in several patients. Circulating B cells are present, but there is a severe reduction of all Ig isotypes with the exception of IgM, which is often elevated. Lymphadenopathy is common and is associated with expansion of germinal centers. Somatic hypermutation is severely compromised in patients with AID deficiency, and follows an abnormal pattern in patients with UNG deficiency.

Treatment is based on regular administration of Igs, as well as prompt recognition and therapy of infections.

Defects in CSR have also been reported in patients with mutations in *INO80* (encoding for a chromatin remodeling complex) and *MSH6* (involved in the DNA mismatch repair pathway). The latter group of patients is at increased risk of cancer.

Other Immunoglobulin Defects

Gain-of-function mutations of the *PIK3CD* gene (encoding for the p110δ catalytic component of PI3K) cause an immunodeficiency characterized by nodular lymphoid hyperplasia, progressive lung disease with bronchiectasis, chronic or recurrent herpesvirus viremia (CMV, EBV, VZV, HSV), and hepatosplenomegaly.[170,171] There is an increased risk of lymphomas, which are not necessarily associated with EBV infection. The immunologic phenotype includes CD4

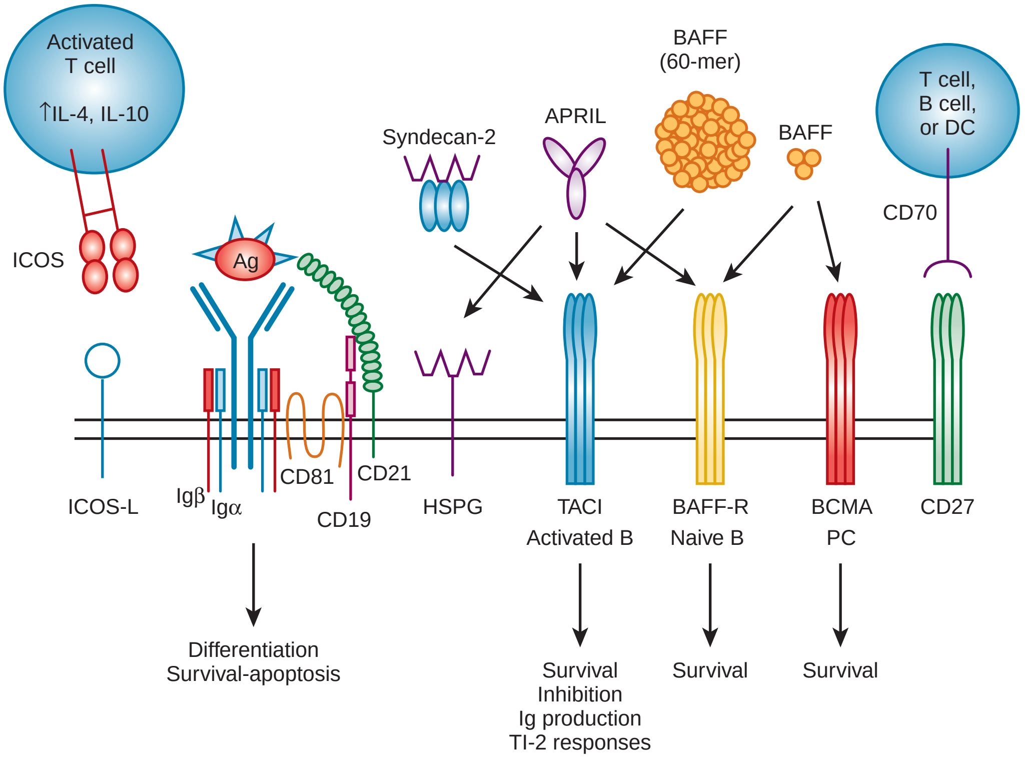

Figure 52.3 GENETIC DEFECTS ASSOCIATED WITH COMMON VARIABLE IMMUNODEFICIENCY (CVID). Schematic of cell surface molecules expressed on B cells and their ligands, highlighting those in which defects have been shown to be associated with CVID. *Ag*, Antigen; *APRIL*, a proliferation-inducing ligand; *BAFF*, B-cell–activating factor; *BAFFR*, B-cell–activating factor receptor; *BCMA*, B-cell–maturation antigen; *DC*, dendritic cell; *HSPG*, heparin sulfate proteoglycan; *ICOS*, inducible T-cell costimulator; *ICOS-L*, inducible T-cell costimulator ligand; *Ig*, immunoglobulin; *IL-4*, interleukin 4; *IL-10*, interleukin 10; *PC*, plasma cell; *TACI*, transmembrane activator and calcium modulator and cyclophilin ligand interactor; *TI-2*, T-cell–independent type 2.

DIAGNOSTIC AND THERAPEUTIC APPROACH TO DEFECTS IN HUMORAL IMMUNITY

- Defects in humoral immunity may be caused by intrinsic defects in B-cell development and function, or caused by combined immunodeficiency disorders where lack of T-cell help is the primary cause of B-cell dysfunction.
- Age-specific norms must be used for children. Immunoglobulin (Ig) G levels at birth reflect the maternally transferred antibody, which nadir between 2 and 6 months, then progressively rise with age. IgA and IgM levels rise continually with age until the teenage years.
- Based on enumeration of T, B and natural killer cells, X-linked agammaglobulinemia (XLA; absence of B cells) can be rapidly ruled out.
- The finding of hyper-IgM with low IgG should prompt a work-up for CD40L deficiency, CD40 deficiency, activation-induced cytidine deaminase (AID), and uracil-DNA glycosylase (UNG). The likelihood of each of these is of course different depending on gender and family history. It is important to note that CD40L deficiency may present with a normal IgM.
- The diagnosis of common variable immunodeficiency disorders (CVIDs) should only be made once other causes have been ruled out, and should be made with caution, if at all, in children under 4 years of age. Disorders such as XLA, autosomal recessive agammaglobulinemia, various hyper-IgM syndromes, and XLP should be specifically considered and ruled out. Other diseases that may masquerade as CVID include other combined immunodeficiencies, cystic fibrosis, HIV, and conditions leading to Ig loss such as protein-losing enteropathy. Medications may mimic the symptoms of CVID. Finally, in adults hypogammaglobulinemia may herald the development of thymoma or lymphoid malignancies, and therefore may be secondary to evolving neoplasia.
- Treatment of XLA and the hyper-IgM syndromes other than CD40LG deficiency is long-term intravenous Ig replacement, which is very effective.
- Experts disagree on whether CD40LG deficiency should be treated with early SCT, and currently there are no clear predictors to determine who is likely to suffer from opportunistic infections. A patient with CD40LG deficiency who has developed cryptosporidium infection and sclerosing cholangitis generally has a much worse outlook with SCT. However, outcomes have generally improved in recent years.
- Treatment of CVID with SCT is generally reserved for those with another requirement for SCT such as developing a lymphoid malignancy or lymphoproliferation, which requires continual immunosuppression.

cell lymphopenia, a reduced proportion of naïve T cells, expansion of effector memory and “exhausted” $CD8^+$ T cells, defective T-cell proliferation, variable Ig levels (often with low IgG2), reduced proportion of memory B cells, and poor antibody responses. In these patients, increased PI3K signaling causes hyperactivation of the AKT–mammalian target of rapamycin (mTOR) pathway, shifting the intracellular metabolism of lymphoid cells towards glycolysis and thereby deranging lymphocyte function and differentiation.

A very similar clinical and laboratory phenotype has been observed in patients with heterozygous mutations of the *PIK3R1* gene (encoding for the p85α regulatory subunit of PI3K), which permit expression of a mutated p85α protein lacking the p110δ-interacting domain.[172–174] Treatment with rapamycin, to reduce mTOR activation, may be beneficial in both conditions. An alternative strategy, currently under investigation, is based on the use of PI3K inhibitors.

CHAPTER 53

PEDIATRIC AND ADULT HISTIOCYTIC DISORDERS

Adi Zoref Lorenz, Olive S. Eckstein, Nitya Gulati, Michael B. Jordan, and Carl E. Allen

The histiocytic disorders comprise a broad grouping of hematologic and immunologic diseases united by aberrant function, differentiation, and/or proliferation of cells of the mononuclear phagocyte system. The term *histiocyte* historically referred to tissue phagocytes but now more precisely defines cells of the monocyte/macrophage lineage (Fig. 53.1). The ontogeny of these cells and their role(s) in pathogenesis continue to be studied and refined. In the 1970s, Steinman and Cohn distinguished dendritic cells (DCs) from macrophages based on specific morphologic features of DC and superior antigen-presenting capacity.[1,2] The characteristic cells seen in various histiocytic lesions can, in general, be differentiated by a variety of functional and phenotypic markers.[3,4] The current classification of the histiocytoses is based on histological comparisons to physiologic "histiocytes" (Table 53.1; Fig. 53.2).[5] Updated classification including features of differentiation, genetic lesions, and tissue involvement has been proposed (Table 53.2).[6] Although malignant disorders involving monocyte/macrophages or dendritic cells are included in this classification, this chapter focuses solely on non-malignant histiocytic disorders.

Of the dendritic cell-related histiocytoses, the most clinically common and prominent one is Langerhans cell histiocytosis (LCH). This chapter also briefly discusses related histiocytic disorders, including juvenile xanthogranuloma (JXG); Erdheim-Chester disease (ECD); and sinus histiocytosis with massive lymphadenopathy (SHML), also referred to as *Rosai-Dorfman disease* (RDD). These conditions are now recognized as myeloid neoplastic disorders characterized by recurrent mitogen-activated protein kinase (MAPK) pathway–activating mutations.

Unlike LCH and related disorders, hemophagocytic lymphohistiocytosis (HLH) is a reactive immune disorder where activated macrophages observed in tissue biopsies reflect coordinated immune dysfunction of interactive partners including activated T cells and defective natural killer (NK) cells.

Table 53.1 lists a currently accepted classification of histiocytic disorders, and Table 53.2 outlines a proposed revision. These disorders are a diverse grouping ranging from benign skin lesions to rapidly life-threatening systemic disorders. Tables 53.3 and 53.4 outline clinical features and commonly used histologic markers or pathologic features that may be used to help distinguish some of these disorders. The clinical diversity of histiocytic disorders is underscored by recent discoveries related to their pathogenesis.

LANGERHANS CELL HISTIOCYTOSIS

LCH is the most common histiocytic disorder.[7] The physiologic epidermal Langerhans cell was first described in 1868 by 21-year-old medical student Paul Langerhans, though he initially described it as a nerve cell.[8] In the early 1900s, Hand, Schüller, and Christian described the various presentations of LCH, which include lytic bone lesions, skin rash, and central diabetes insipidus (DI).[9–11] Letterer and Siwe described more severe aggressive and rapidly fatal cases with liver and spleen involvement in young children.[12,13] These disorders were later grouped under the term *histiocytosis X* by Lichtenstein based on common histologic appearance and uncertain cell of origin.[14] Nezelof subsequently theorized that histiocytosis X was caused by a proliferation of pathologic Langerhans cells (LC) due to a common feature of Birbeck granules identified by electron microscopy.[15] At present, *"Langerhans cell histiocytosis"* is typically accepted as the universal terminology replacing all previous nomenclature to refer to all varied clinical presentations of this protean disorder, though recent discoveries identify cells of origin as myeloid precursor cells rather than differentiated epidermal LC.[7] LCH can present at any time in life from the neonatal period to old age. LCH lesions may spontaneously regress or repeatedly "reactivate," contributing to long-term disabilities such as endocrinopathies or a neurodegenerative disease.

Epidemiology

The incidence of LCH has been estimated to be between 5 and 10 cases per million children, per year.[16] While the incidence of LCH in adults is thought to be lower and estimated at 1 case per million adults per year, it is likely underdiagnosed in adults due to the under-recognition of LCH in adult medicine.[17,18] Recent registry studies suggest an increased incidence in Hispanic populations and a significantly lower incidence in African Americans.[19] Further, a genome-wide association study (GWAS) trio study identified an increased risk of LCH in patients with a *SMAD6* variant that is enriched in Hispanic populations.[20] Although families with multiple cases of LCH have been reported, these events are extremely rare. LCH may rarely arise as a shared clone with other hematologic malignancies, most notably in adults with myeloid histiocytic disorders as part of myeloid neoplasias associated with clonal hematopoiesis.[21]

Pathophysiology

Over the past decade, there has been a significant evolution in the scientific understanding of the biologic mechanisms leading to LCH, driven by new insights in both normal epidermal and disease-associated LC.[7,22] Prior to these more recent discoveries, LCH was variably classified as a neoplasm, a reactive disorder, or an aberrant immune response and thought to arise from transformed or pathologically activated epidermal LC. Like epidermal LC, LCH lesion LC express CD1a and CD207 (langerin) surface markers. The frequency of LC within LCH lesions is highly variable, with a median of about 8%. The balance of this granulomatous lesion includes lymphocytes (primarily T cells), eosinophils, and macrophages.

Two studies demonstrated that pathologic LCH cells have clonal properties based on clonal X-chromosome inactivation.[23,24] Additionally, expression studies of pathologic LCH cells from lesions and epidermal Langerhans cells found in skin have demonstrated that pathologic LCH cells have relatively increased expression of immature myeloid dendritic-cell precursors and are therefore likely to derive from abnormal bone-marrow precursor cells or their differentiated ontogeny.[25] Further, several recent studies demonstrated that the expression of *langerin/CD207* is not exclusive to epidermal LC but rather that it can be induced in cells from multiple hematopoietic lineages.[22]

The discovery of recurrent *BRAF*V600E somatic mutations in LCH lesions supports a neoplastic etiology for LCH.[26] BRAFV600E is observed in ~8% of all human cancers and also in benign neoplastic conditions such as melanocytic nevi. Constitutive activation of a MAPK pathway leads to activation of the terminal extracellular signal-related

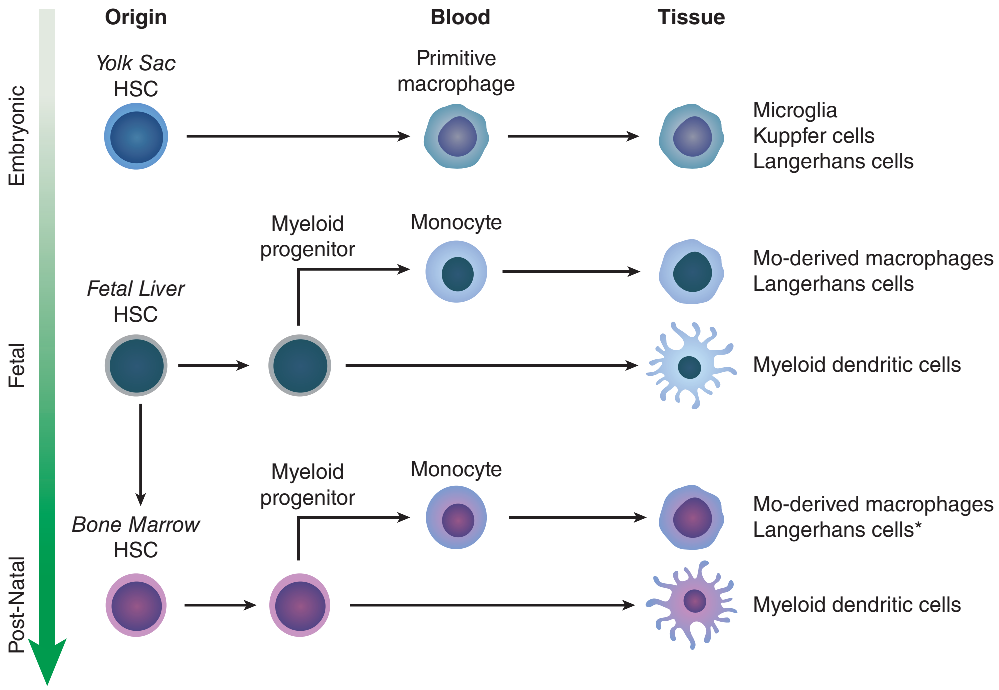

Figure 53.1 ONTOGENY OF TISSUE "HISTIOCYTES." Tissue macrophages and dendritic cells seed tissues at various stages of development. Microglia, Kupffer cells, and Langerhans cells (LCs) arise from yolk sac-derived progenitors, followed by fetal liver, and then adult hematopoiesis. *Langerhans cells may be generated from adult HSC monocyte-derived LCs following inflammation or tissue damage.

TABLE 53.1 **Historical Classification of Histiocytic Disorders**

A. Dendritic cell–related
  Langerhans cell histiocytosis
  Juvenile xanthogranuloma and related disorders including:
  - Erdheim-Chester disease
  - Solitary histiocytomas with juvenile xanthogranuloma phenotype
  - Secondary dendritic cell disorders

B. Monocyte/macrophage–related
  Hemophagocytic lymphohistiocytosis: familial and sporadic
  Secondary hemophagocytic syndromes
  - Infection-associated
  - Malignancy-associated
  - Autoimmune-associated
    Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
    Solitary histiocytoma of macrophage phenotype

kinase (ERK). Several groups have confirmed recurrent *BRAF*V600E in 50% to 64% of LCH cases as well as mutually exclusive activating mutations in MAPK pathway genes (primarily alternative BRAF mutations or mutations in *MAP2K1* [encodes MEK1]) (Fig. 53.3).[27]

Taking advantage of the *BRAF*V600E discovery in LCH lesions, subsequent studies identified *BRAF*V600E in hematopoietic stem cells from bone-marrow aspirate and myeloid precursors from peripheral blood of patients with disseminated LCH.[28] Interestingly, BRAFV600E+ peripheral blood mononuclear cells were rarely observed in patients with more limited "low risk" LCH. A pathogenic role for BRAFV600E in myeloid precursors is further supported by recapitulation of an LCH-like phenotype in mice in which *BRAF*V600E expression was enforced in CD11c+ cells. The "Misguided Myeloid Differentiation" model suggests that the stage of myeloid precursor in which this mutation develops is related to the differentiation potential of the pathologic cell that determines the extent and severity of disease.[7] These observations support the reclassification of LCH as an inflammatory myeloid neoplastic disorder.

Clinical Presentations

The clinical manifestations of LCH can be highly variable, with bony lesions (~80% of cases) as the most common site of disease (Fig. 53.4).[29] Skin involvement is highly pleiotropic and can mimic many common infant skin rashes. Soft tissue swelling, often in proximity to bony lesions, external ear drainage, enlargement of lymph nodes and thymus, and gum hypertrophy with premature eruption of baby teeth are also typical manifestations. More serious systemic involvement occurs when there is hepatosplenomegaly, liver dysfunction, and hematopoietic failure, typical of the widely disseminated form of LCH seen in young infants, and is associated with a high mortality rate.

Bony Involvement

Solitary or multifocal bone lesions are found predominantly in older children and young adults, usually within the first three decades of life. Such lytic bone lesions have commonly been referred to as *eosinophilic granuloma* because of their pathologic appearance, though we prefer consistent nomenclature of *isolated*, *multifocal*, or *multisystem* LCH of bone. The incidence of bone lesions peaks between 5 and 10 years of age. Solitary or multifocal LCH bone lesions (with or without the involvement of other organ systems) represent approximately 60% to 80% of all instances of LCH. These bone lesions often cause abnormal gait or inability to bear weight and may have tender swelling caused by soft tissue infiltrates overlying the bone lesions.

The most frequent sites of skeletal involvement include the flat bones of the skull, ribs, pelvis, and scapula (see Fig. 53.3H). There may be extensive involvement of the skull, with multiple irregularly shaped, lucent lesions giving rise to the so-called *geographic skull*. Involvement of the vertebral bodies may lead to collapse (*vertebra plana*) as the principal or only presenting manifestation. In such cases, the diagnosis may be problematic, although biopsy is typically not

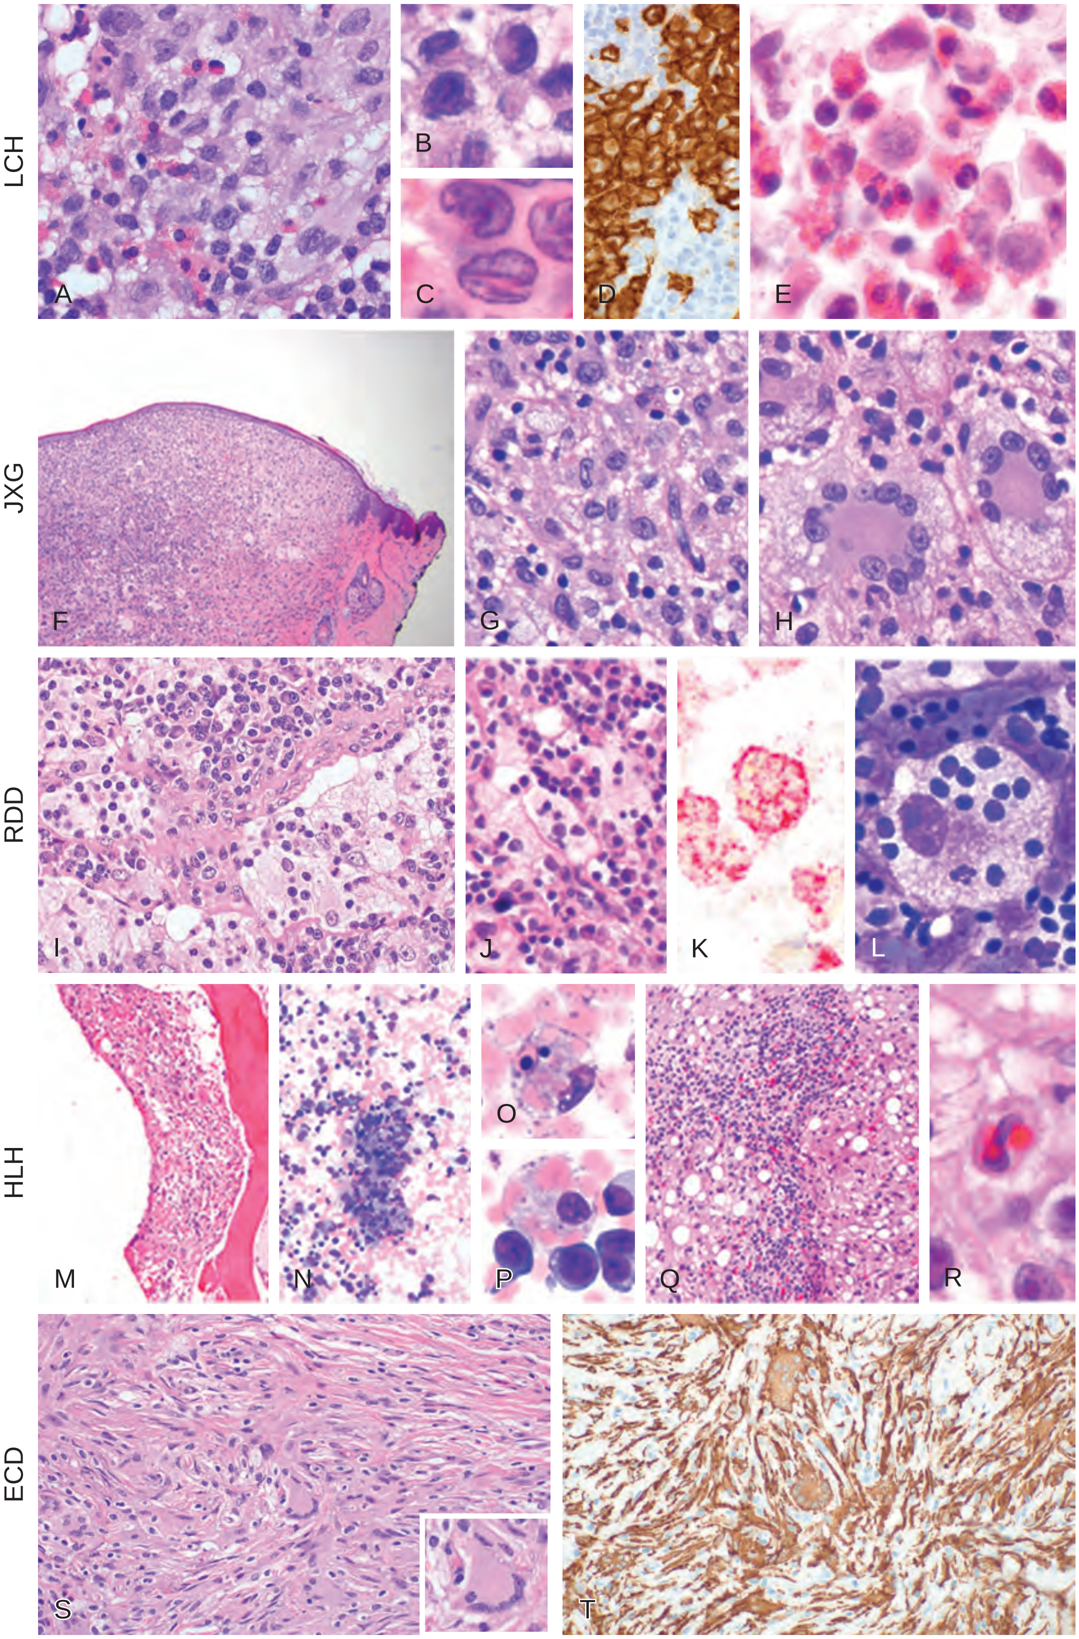

Figure 53.2 HISTOLOGY OF LANGERHANS CELL HISTIOCYTOSIS (LCH), JUVENILE XANTHOGRANULOMA (JXG), HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH), ERDHEIM-CHESTER DISEASE (ECD), AND ROSAI-DORFMAN DISEASE (RDD). ***LCH:*** (A) Biopsy sample showing sheets of histiocytes with abundant pink cytoplasm and folded nuclei with prominent nuclear grooves. (B and C) Cells with a central longitudinal nuclear groove, giving the cell a coffee bean appearance. (D) Immunohistochemical stain for CD1A showing the histiocytic cells are positive. (E) Some cases of Langerhans histiocytosis are associated with prominent eosinophilia. ***JXG:*** Histologic features of juvenile xanthogranuloma vary. (F) In this case, low-power magnification shows a dome-shaped lesion with an attenuated epidermis. (G) At higher power, the bulk of the lesion is composed of a proliferation of histiocytes with abundant pink cytoplasm. Sometimes these histiocytes show more vacuolization or xanthomatization. (H) Scattered Touton-type giant cells are present. ***RDD:*** Low-power magnification of the biopsy sample (I) shows a mottled appearance of the lesion caused by dark areas containing small lymphocytes and lighter areas

(*Continued*)

TABLE 53.2 **Proposed Revised Classification of Histiocytoses**

L Group	LCH
	Intermediate-cell histiocytosis (ICH)
	Erdheim-Chester disease (ECD)
	Mixed LCH/ECD
C Group	Cutaneous non-LCH
	Xanthomatous granuloma (XG) family: includes JXG
	Non-XG family: includes cutaneous RDD
	Cutaneous non-LCH with major systemic component
	XG family: xanthoma disseminatum
	Non-XG: multicentric reticulohistiocytosis
R Group	Familial RDD
	Sporadic RDD
	Classic RDD
	Extranodal RDD
	RDD with neoplasia or immune disease
	Unclassified
M Group	Primary malignant histiocytosis
	Secondary malignant histiocytosis
H Group	Primary HLH
	Secondary HLH (non-Mendelian)
	HLH of unknown/uncertain origin

ECD, Erdheim-Chester disease; *HLH*, hemophagocytic lymphohistiocytosis; *JXG*, juvenile xanthogranuloma; *LCH*, Langerhans cell histiocytosis; *RDD*, Rosai-Dorfman disease.

advisable unless a soft tissue mass is present. In long bones, growth of lesions in the medullary cavity leads to pressure that may result in erosion through the cortex, stimulating the formation of periosteal new bone accompanied by soft tissue extension. The differential diagnosis includes Ewing and osteogenic sarcoma, bone lymphoma, benign bone tumor and cyst, and infection. Involvement of distal bones such as the wrists, hands, or feet is less common. Orbital involvement may result in vision loss or strabismus caused by optic nerve or orbital muscle involvement, respectively, and may mimic pre-septal cellulitis. Signs and symptoms may include bony defects with exophthalmos, with a characteristic tumor mass in the orbital cavity related to disease arising from the roof and lateral wall of the orbital bone. Oral involvement commonly affects the gums, palate, or both. In addition, teeth may be lost due to maxillary or mandibular involvement with or without oral mucosal gum infiltration. Erosion of the lamina dura gives rise to the characteristic "floating tooth" seen on dental radiographs. Erosion of gingival tissue causes premature eruption, decay, and tooth loss. Parents of affected children, particularly infants, frequently report precocious eruption of teeth when, in fact, the gums are receding, leading to the exposure of immature dentition. Chronic otitis media is caused by involvement of the mastoid and petrous portion of the temporal bone, leading to otitis externa manifesting as chronic otorrhea is common (see Fig. 53.3J).

Cutaneous Involvement

Cutaneous involvement by LCH is both common (occurring in 20% to 40% of patients) and highly variable and can mimic more common skin conditions of children. The rash is typically a scaly seborrheic, eczematoid, sometimes purpuric rash involving the scalp, ear canals, abdomen, and intertriginous areas of the neck, face, trunk, and groin (see Fig. 53.4C–F). Ulceration may result, especially in intertriginous areas, and may be painful. Mild, isolated cutaneous involvement is relatively common in young infants. Rarely, LCH may present only as subcutaneous skin nodules (formerly described as *Hashimoto–Pritzker syndrome*), most often in young infants. In many cases of skin-limited neonatal LCH, the lesions may spontaneously resolve.

Involvement of Other Organ Systems

A subset of infants and toddlers with LCH have spleen, liver, or bone-marrow (BM) involvement, often in addition to prominent skin involvement and variable bony disease. This potentially fatal clinical phenotype is the most severe manifestation of LCH. Liver involvement may be clinically problematic, leading to significant cholestasis, hypoproteinemia, diminished synthesis of clotting factors, and ultimately sclerosing cholangitis.

LCH can rarely present with lymph node-limited disease that may be difficult to distinguish SHML, also known as RDD. This presentation is characterized by significant enlargement of multiple lymph node groups with little or no other signs of disease. Thymic involvement is relatively common in children with multisystem involvement but can also be isolated. Gastrointestinal tract disease is rare but is sometimes associated with severe symptoms of diarrhea, hematochezia, malabsorption, and hypoproteinemia. Pancreatic, thyroid, and thymus disease has also been reported.

Isolated pulmonary involvement is usually seen in young adults in their third or fourth decades of life, and occasionally in children and adolescents. It may follow a severe and often chronic debilitating course and patients may often present with spontaneous pneumothorax. Cigarette smoking has been strongly implicated in primary pulmonary histiocytosis. Findings on chest radiographs vary from a diffuse infiltrate consistent with bilateral interstitial pneumonia to a "honeycomb lung" appearance with nodules and cysts (see Fig. 53.4G).

Other Clinical Features

Central DI affects 5% to 40% of patients with LCH.[30] Most instances of DI occur in children who present with systemic disease and involvement of the orbit and skull. DI is caused by infiltration by LC and immune infiltrate into the hypothalamus with or without the involvement of the posterior pituitary gland (see Fig. 53.4K). Most cases of DI present within the first 4 years of diagnosis, although it may occur at any time during the course of LCH. Definitive documentation of DI with measurement of serum and urine electrolytes and osmolality before and after a several-hour water deprivation period should be performed, usually in consultation with an endocrinologist. Antidiuretic hormone (ADH) levels can also be measured to document deficiency, although they are not required for diagnosis. DI

---

containing histiocytes. At higher magnification (J), the histiocytes have abundant pale cytoplasm with scattered cells within. This is emperipolesis, a process of cells traveling through the cytoplasm but not apparently becoming phagocytized or degraded. Note the plasma cells in the background. The emperipolesis can be better visualized with a CD68 stain for histiocytes (K). This process delineates the cell boundary and the cells within the histiocyte cytoplasm. The emperipolesis can also be seen on a Wright-stained touch preparation (L). ***HLH*** Illustrations from a 3-month-old girl who presented with diarrhea, pancytopenia, hepatomegaly, and liver failure. Bone marrow (M and N) showed left-shifted granulopoiesis and increased histiocytes, which at high power (O and P) were undergoing prominent phagocytosis of erythrocytes, platelets, and other cells. Liver biopsy sample (Q) showed a lymphohistiocytic infiltrate also associated with hemophagocytosis (R). The patient was shown to harbor a mutation of the perforin gene in exon 2. ***ECD:*** Lower magnification biopsy of skin from a patient involved by ECD characterize by dermal infiltrate (S) of bland appearing histiocytes characterized by abundant foamy (xanthomatous) cytoplasm with surrounding fibrosis. Note the multinucleated Touton giant cell in the inset. The cells are positive by histiocytic marker CD163 (T).

TABLE 53.3 Clinical Features of the Non-Langerhans Cell Histiocytosis, Non-Hemophagocytic Lymphohistiocytoses

Diagnosis	Ages	Lesions (*n*)	Appearance	Common Sites	Natural History
JXG	0–18 years (median, 2 years)	Single: multiple 9 : 1 (disseminated in <6 months)	Reddish progressing to yellow brown	Head and neck	Gradual involution
Giant JXG	Young	Single	>2 cm	Upper extremity or back	Involution
Systemic JXG	(3 months[a])	Single-multiple	Almost 50% have no skin lesions	Subcutis, liver, spleen, lung, CNS, iris	May involute (4%–10% fatal)
Adult XG	18–80 (35 years[a])	Single	Same as JXG	Upper body	No involution
BCH	Young child	Few-multiple	Reddish-tan papules	Head and neck	Involution or progression to XG
GEH	Young adult	Disseminated	Reddish-tan papules in crops	Face, trunk, arms	Involution or progression
XD	Young adult	Disseminated	Yellow/reddish-brown plaques and nodules	Eyelids, mucosae, viscerae, CNS	Slow involution or progression
PNH	40–60 years	Disseminated	Xanthoma, nodules	Skin, subcutis	Progression to disfigurement
MRH	>40 years	Multiple	Pink/reddish-brown or yellow	Head, extremities with erosive polyarthritis	Progression
SHML	Wide age range (20 years[a])	Mainly systemic	Firm indurated papules	Cervical adenopathy, 80% “B” symptoms, extranodal (43%)	Exacerbations and remissions (5%–11% fatal)
ECD	7–84 years (53 years[a])	Mainly systemic	Xanthelasma, xanthoma	Long-bone sclerosis, retroperitoneal fibrosis	Highly fatal

[a] Approximate median age of presentation.

typically persists beyond successful LCH therapy, requiring life-long management with desmopressin.

Short stature has been found in up to 40% of children with systemic LCH. Chronic illness and steroid therapy are believed to play an important role in this phenomenon. However, short stature also may be a consequence of anterior pituitary involvement and growth hormone deficiency, which can occur in up to half of patients with initial anterior pituitary dysfunction. Other endocrine manifestations associated with LCH may include adrenal insufficiency, hyperprolactinemia, or hypogonadism caused by hypothalamic infiltration.

One of the most severe complications of LCH is the development of a progressive central nervous system (CNS) neurodegenerative syndrome (LCH-ND).[30] This syndrome may develop with the onset of LCH or more typically years after the patient is presumed to be cured. Increased risk of LCH-ND has been associated with “CNS-risk” bone lesions (orbit, mastoid, maxilla, temporal, sphenoid, zygomatic, clivus), pituitary lesions, and *BRAF*V600E mutations. Delayed CNS involvement is typically diagnosed after a prolonged, sometimes insidious, decrease in cognitive abilities/school function. Magnetic resonance imaging (MRI) characteristically reveals diffuse or polymorphic lesions involving the white matter of the cerebellum, pons, basal ganglia, and less often the cerebral hemispheres with T2 hyperintensity (see Fig. 53.4L). Limited biopsy studies have previously revealed an inflammatory infiltrate, dominated by $CD8^+$ T cells, initially suggestive of a paraneoplastic or autoimmune phenomenon. More recently, analysis of brain biopsy and autopsy specimens showed perivascular infiltrates of BRAFV600E+ monocytes and microglia-like cells at sites of neurodegeneration, suggesting that neurodegenerative disease likely represents an active form of LCH rather than an autoimmune or paraneoplastic phenomenon.[31] Of note, although abnormal MRI findings (with white matter lesions) may precede clinical manifestations, such findings do not always correlate with clinical disease (even in retrospect) and do not always progress. Therapy for LCH-ND is controversial. Reports suggest the potential for responses in early disease with LCH-directed chemotherapy and/or MAPK pathway inhibitors.[32,33]

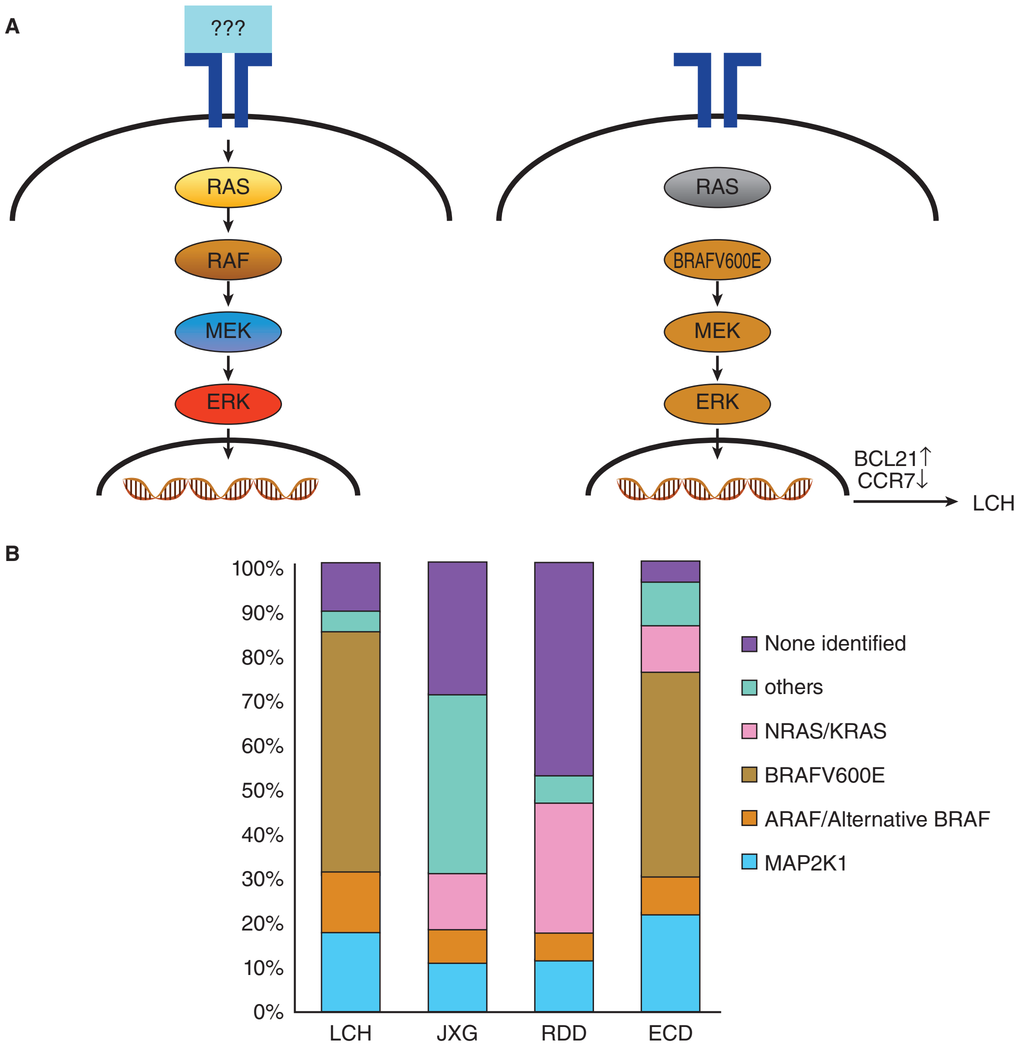

Figure 53.3 MAPK PATHWAY MUTATIONS IN HISTIOCYTIC DISORDERS. (A) (*Left*) Schematic of MAPK pathway. Under physiologic conditions, growth factor (*gray* box) engages tyrosine kinase receptor that transduces signal to nucleus. (*Right*) Activating mutations (such as BRAF-V600E) drive constitutive ERK activation. In the case of Langerhans cell histiocytosis (LCH), this drives expression of anti-apoptosis BCL2L1 *(BCL-xL)* and inhibits CCR7. (B) Stacked bar graphs represent percentages of MAPK pathway mutations in each histologic subtype of histiocytosis. *ECD*, Erdheim-Chester disease; *JXG*, juvenile xanthogranuloma; *LCH*, Langerhans cell histiocytosis; *RDD*, Rosai-Dorfman disease.

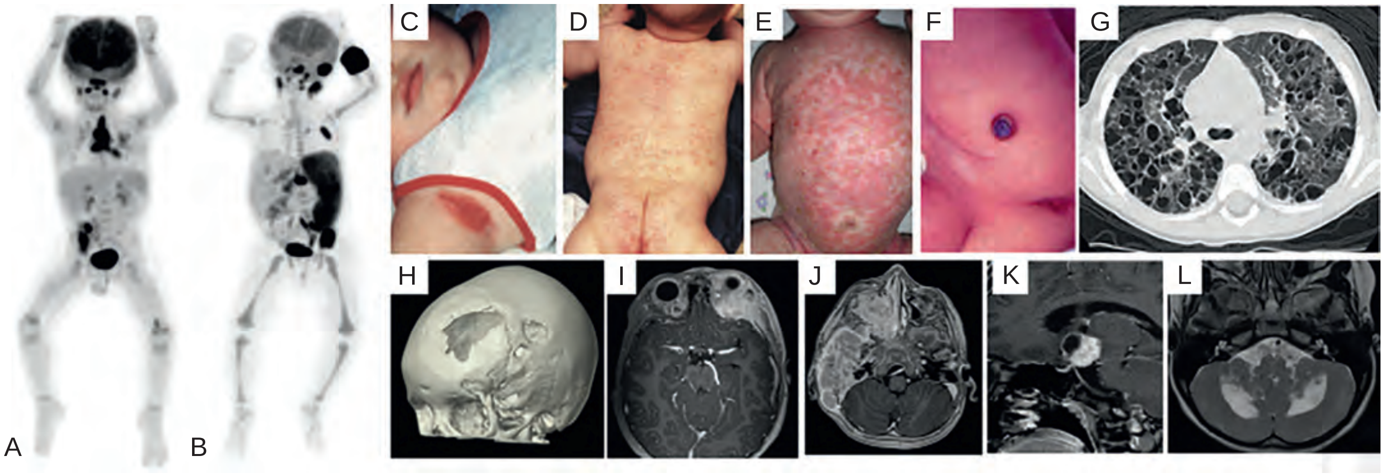

Figure 53.4 CLINICAL PRESENTATIONS OF LANGERHANS CELL HISTIOCYTOSIS (LCH). (A) PET-CT of patient with low-risk LCH including thymus, pelvis, and femur lesions; (B) PET-CT of patient with high-risk LCH including spleen, LN, and multifocal bone lesions; (C–F) various LCH skin lesions; (G) CT scan of pulmonary LCH; (H) CT demonstrating typical multifocal skull lesions; (I) orbital lesion in patient presenting with proptosis; (J) extensive skull/mastoid lesions; (K) pituitary lesion; and (L) LCH-associated neurodegenerative disease with typical T2-hyperintensity of cerebellum and pons on MRI.

Laboratory Manifestations

Tables 53.3 and 53.4 list the clinical and pathologic features that help to describe and distinguish LCH from other, much rarer, histiocytic disorders. The CD1a+/CD207+ LC is the essential diagnostic feature in the histology of LCH. Mitoses are rare. Multinucleated giant cells may be present. Other inflammatory cells, such as granulocytes, eosinophils, macrophages, and lymphocytes, are also present in variable numbers. The diagnosis of LCH relies on the immunohistochemical identification of the presence of LC by characteristic appearance with reniform nuclei and CD1a+/CD207+ by immunohistochemistry (see Fig. 53.2A–E).[34,35] Electron microscopy can identify Birbeck granules but is currently rarely used. Notably, CD207 expression levels may be variable within lesions and may be absent from liver, brain, or BM lesions. There are no predictive pathologic features that may define "favorable" or "unfavorable" histology. Immunohistochemistry, qualitative or quantitative PCR, and/or targeted sequencing may be used to identify *BRAF*V600E to support the diagnosis of LCH and also for risk-stratification. Additionally, high-sensitivity PCR of peripheral blood or BM mononuclear cells can identify BRAFV600E+ hematopoietic precursors, and the presence of which is associated with disseminated disease.[28]

Patients who are suspected to have LCH or who have a new biopsy-proven diagnosis of LCH should have imaging to determine the extent of disease. Positron emission (PET) scanning is highly sensitive for LCH.[36] Initial studies including a complete blood count, chemistries including liver function tests, coagulation workup, and urine osmolality are also warranted. Dental examination and radiographs should also be considered depending on clinical history and exam. The occurrence of cytopenias, particularly thrombocytopenia, in the presence of liver or spleen involvement may suggest BM involvement. We typically perform BM studies for all patients under the age of two years old and patients with liver or spleen disease, regardless of complete blood count (CBC) results.

Differential Diagnosis

The differential diagnosis of LCH depends on the clinical presentation and is typically elucidated with a tissue biopsy. Skin involvement may mimic seborrheic dermatitis, albeit with a severe or refractory course. Immunodeficiency syndromes or viral infection must be considered as well. The differential diagnosis of bony lesions, although typically quite distinctive, may include bone cyst, non-ossifying fibroma, lymphoma, sarcoma, or metastatic solid tumor. Chronic otorrhea due to temporal bone involvement is often initially misdiagnosed as chronic otitis media. Liver and spleen involvement must be distinguished from leukemia, infection, and metabolic storage diseases. The new onset of DI may also arise from germinoma or pituitary hypophysitis.

Prognosis

The prognosis of patients with LCH is largely determined by the extent of disease and response to initial therapies. In general, the population with the highest risk of mortality includes patients with visceral, or so-called "high risk organ" involvement (e.g., liver, spleen, and/or BM). Furthermore, the International Histiocyte Society conducted a clinical trial (LCH-II) that identified the response after an initial 6 weeks of therapy with weekly vinblastine and daily prednisolone as a risk factor in predicting mortality in patients with risk organ involvement.[37] Of the approximately 79% of patients who responded to initial therapy, 94% were alive at 5 years, but only 11% of the non-responders survived. These important data suggest that alternative therapies should be tested early during the course of therapy for patients with poor early responses. Additionally, *BRAF*V600E mutation is associated with increased risk of refractory disease/relapse and LCH-ND.[28,33,38]

Therapy

A generally accepted standard for the initial treatment of patients with LCH is the use of an appropriate amount of the least toxic therapy to treat the disease. Isolated skin lesions may spontaneously resolve or respond to topical therapies. Single bone lesions may be treated with curettage and/or steroid injection, with exceptions for functionally critical lesions that are not amenable to surgery and sites of disease that are considered CNS-risk. Patients with multifocal and multisystem disease typically require systemic therapy.[39,40]

Surgery and Radiotherapy

Patients with disease involving a single bone can usually be managed with local therapy in consultation with surgical subspecialists. This most often involves surgical curettage or intralesional steroid injection for patients whose lesions are in easily accessible and non-CNS risk locations. Overly aggressive complete "cancer operation" resections are contraindicated and may impair remodeling that typically occurs if margins remain intact. Limited local radiotherapy may be indicated for rare circumstances where an isolated lesion is inaccessible.

Chemotherapy

Historically, systemic treatment of LCH has used chemotherapy drugs classically used for malignant diseases. Therapeutic advances for LCH in recent years have largely come from international cooperative trials testing empiric chemotherapeutic strategies conducted by the Histiocyte Society. LCH-III demonstrated lower relapse rates in patients treated with 1 year versus 6 months of vinblastine/prednisone. Further, the addition of methotrexate to patients with high-risk LCH was not beneficial.[41] Therefore, the current standard of care for patients requiring chemotherapy for LCH includes vinblastine/prednisone for 1 year (with mercaptopurine added for high-risk LCH). The Histiocyte Society is currently testing the impact of further treatment prolongation (2 vs. 1 year) with vinblastine/prednisone/(mercaptopurine for high-risk) for frontline therapy (clinicaltrials.gov: NCT02205762). Based on responses to cytarabine monotherapy in an institutional series, another phase III trial is currently testing 1 year of vinblastine/prednisone/mercaptopurine versus cytarabine for frontline LCH (clinicaltrials.gov: NCT00276757).[42]

Alternative treatment has not been standardized for patients with recurrent or refractory disease. Patients with recurrent disease (i.e., disease that reappears after a period of remission) may respond to reinitiation of the drugs with which they were initially treated. Several studies, including an international phase II trial, have demonstrated significant activity of nucleoside analogs (2-chlorodeoxyadenosine [2-CdA], cytarabine, and clofarabine) against recurrent and refractory LCH. The combination of 2-CdA and high-dose cytarabine has high response rates, but also notable treatment-related mortality.[43] Moderate dose cytarabine and clofarabine have been reported as effective in institutional series.[42,44] Prospective trials are required to determine the optimal agents and doses. Hematopoietic cell transplant has also been reported as successful in some extreme cases of disseminated LCH.[45]

Since the discovery of the central pathologic role of MAPK pathway activation, BRAF-V600E and MEK inhibitors have been utilized primarily as salvage therapies with extremely high response rates.[32,46–49] However, disease typically recurs with cessation of therapy and the toxicity profiles are not ideal for life-long use. Pre-clinical studies and clinical trials are required to determine optimal timing, duration, and potential combination therapies with MAPK inhibitors.

Long-Term Follow-Up

Over 50% of LCH survivors experience at least one permanent consequence, with more frequent long-term effects in patients with multisystem disease and multiple relapses.[51] The most commonly reported late effects are DI and orthopedic abnormalities. Complications of developing DI include a significant incidence of anterior pituitary hormone deficiencies and an associated risk for later developing neurodegenerative syndrome. Patients with LCH-ND typically present with ataxia, dysarthria, dysmetria, and learning and behavior difficulties. The diagnosis may be aided by brain MRI, in which T2 hyperintense signals in the cerebellum, basal ganglia, or pons may be present, although such abnormalities do not always correlate with clinical disease and vice versa is also true (see Fig. 53.4). Treatment with low-dose cytarabine or MAPK inhibition has anecdotally resulted in stabilization or improvement of these symptoms.[30,31,33]

The small but real risk of secondary malignancy in patients with LCH undergoing radiation and chemotherapy is well documented. Thus, judicious use of radiotherapy, avoidance of potentially carcinogenic chemotherapeutic agents, and good supportive care are recommended. Because etoposide was not shown to be any more effective than vinblastine in both the LCH-I and LCH-II trials for patients without risk of organ involvement, there does not appear to be compelling reasons to include this leukemogenic agent in the treatment of patients with newly diagnosed LCH.[37,51] Rarely LCH can occur along with other hematologic malignancies that share a common origin.[52]

Another serious late effect of LCH is sclerosing cholangitis, which may lead to secondary biliary cirrhosis and liver failure. Sclerosing cholangitis may develop years after successful therapy for LCH and does not typically signify disease recurrence. The only successful treatment of sclerosing cholangitis has been liver transplantation, although anecdotal reports with clofarabine and MAPK inhibitors have also shown promise in at least stabilizing this process.

Other late complications of LCH include pulmonary cyst formation, fibrosis, and chronic pneumothoraces, and progression to cor pulmonale and respiratory failure may occur. Lung transplantation has been used for the treatment of such patients. Consequently, all patients with LCH require long-term follow-up.[53]

Future Directions

Frontline vinblastine/prednisone, the current standard of care for systemic LCH, cures fewer than 50% of patients. More effective therapy that minimizes toxicity and the risks of late consequences is clearly needed. With the recent insights into the pathophysiology of LCH, including a central role for MAPK activation in myeloid precursors, new possibilities for rationale, targeted therapies being explored. Ideally, future trials will lead to precision strategies to determine optimal therapy for patients based on features of the patient and disease.

JUVENILE XANTHOGRANULOMATOUS DISEASE

JXG (or more broadly, the full spectrum of juvenile xanthogranulomatous diseases) is a histiocytic disorder with features of macrophage histology. JXG most commonly affects infants and young children, with a slight male predominance and presents as a solitary or a few “fleshy nodules.” The most common sites are the skin of the frontal trunk, head, and neck, but they can occur at any site on the body. These red-yellowish, benign-appearing lesions are sometimes mistaken for molluscum. However, when biopsied, these lesions reveal a distinctive pathology (see Fig. 53.2F–H). Multinucleated, Touton giant cells are usually found, and lesional histiocytes are positive for CD14, CD68, CD163, factor XIIIa, and fascin, historically compared to dermal dendrocytes.[54] The cells are usually negative for CD1a, CD207, S100, plasmacytoid monocyte antigen CD123, and absent Birbeck granules. Lesions may vary significantly in size and number but are often several millimeters to 1 cm in size and solitary. However, in some patients, the lesions become widespread and quite disfiguring (Fig. 53.5). Furthermore, JXG may be systemic (<5% pediatric cases) involving multiple organs, including deeper soft tissue, central nervous system, bone, lung, liver, spleen, pancreas, adrenal glands, intestines, kidneys, lymph nodes, BM, orbit, and heart.[55] CNS involvement can present with seizures, hemiplegia, and increased intracranial pressure. Patients diagnosed with JXG, particularly multifocal JXG, may benefit from screening computed tomography (CT) or MRI scans to rule out disseminated involvement. Ophthalmologic examination may be helpful to rule out anterior chamber involvement and prevent potentially blinding complications.

The etiology of JXG and the basis for prevalence in children and tissue distribution is not well defined. Several cases suggesting an association between JXG, neurofibromatosis (types 1 and 2), and juvenile chronic myelogenous leukemia that potentially implicates MAPK pathway hyperactivity as shared pathogenesis have been reported. Additionally, molecular alteration in the MAPK pathway such as *CSF1R*, *KRAS, NRAS*, and *MAP2K1* (rarely *BRAF*V600E) and PI3K pathway mutations have been identified (see Fig. 53.3).[56]

Cutaneous JXG lesions usually resolve over several months and require no treatment. Of note, residual pigmented areas may persist indefinitely even after lesions have regressed. In patients in whom JXG becomes systemic and involves multiple organs, LCH-based systemic chemotherapy regimens such as vinblastine and steroids, cladribine, and clofarabine has led to responses in some case reports and series.[44,55]

ERDHEIM-CHESTER DISEASE

ECD is a rare, non-Langerhans form of histiocytosis first described in 1930 with a wide range of manifestations. While still extremely uncommon, the number of new cases has increased over the past 10 years because of the better recognition of this condition. The natural evolution is variable, but the prognosis in the absence of effective therapy is poor.[57]

ECD is seen most commonly in patients between ages of 40 to 70 years old, with a male predominance. It usually presents with xanthelasma lesions on the upper eyelids or yellow/red-brown plaques skin rash and bilateral lower limb bone pain. In fact, the consensus diagnostic criteria for ECD require presence of (1) foamy CD68+/CD1a− histiocytes, often with admixed inflammation and fibrosis, and (2) skeletal findings of bilateral and symmetric abnormalities in the diaphyseal and metaphyseal regions of the long bones of the legs. Patients with more disseminated disease may have cardiopulmonary insufficiency; renal failure caused by characteristic retroperitoneal and perinephric infiltrative or constrictive changes; and CNS involvement manifested by cerebellar symptoms such as ataxia, dysarthria, dysphagia or endocrinopathies such as DI, or cognitive decline. They may also have periorbital involvement with exophthalmos and impingement on the optic nerves. Untreated, this disease may be progressive and fatal.[58]

There has been significant advancement in understanding the pathophysiology of ECD over the last decade. ECD is now considered to be a clonal hematopoietic disorder driven by recurrent alterations in the MAPK pathway (*BRAF*V600E being the most common in approximately 50% of patients), with clinical manifestations thought to be due to the neoplastic histiocytic infiltrates and uncontrolled inflammation. A unique inflammatory cytokine signature consisting of elevated interferon-α (IFN-α), interleukin-12 (IL-12), and monocyte chemotactic protein-1 and decreased IL-4 and IL-7 in these patients suggests a systemic immune perturbation associated with ECD pathogenesis.[59]

First-line treatment for ECD has consisted of IFN-α. However, early reports of near-universal metabolic responses to MAPK inhibition led to FDA approval of vemurafenib for BRAFV600E+ ECD, and studies evaluating MEK inhibition are ongoing (NCT04079179, NCT02649972).[47,48,55,60,61] Other effective treatments have been limited, although responses have been observed with steroids, vinblastine plus steroids, anakinra, tocilizumab, methotrexate, 2-CdA, and bisphosphonates. Autologous hematopoietic BMT has also been reported as a therapeutic modality.[57]

ROSAI-DORFMAN-DESTOMBES DISEASE (OR SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY)

Pierre Pail Lois Lucien Destombes first reported four patients with lymphadenopathy and sinus histiocytosis on histology in 1965. In 1969, Juan Rosai and Ronald Dorfman analyzed 34 similar cases that they described as sinus histiocytosis with massive lymphadenopathy.[62,63] SHML, or RDD, can have a widely variable clinical presentation and can occur as an isolated disorder or in association with other autoimmune, malignant, or hereditary diseases. The most common clinical presentation is that of chronic, painless massive lymphadenopathy usually involving cervical lymph nodes and, less frequently, axillary, hilar, peri-tracheal, and inguinal nodes with or without intermittent fevers, night sweats, and weight loss (Fig. 53.6).[64]

Extranodal disease is present in approximately 43% of patients, with multisystem involvement present in 19% of cases. Skin involvement (painless, nonpruritic nodules, plaques, or papules) is present in 10% of extranodal RDD cases, though it is rarely isolated. The upper respiratory mucosa (sino-nasal, oral cavity including salivary glands, parotid gland, larynx, pharynx, thymus or thyroid gland) may also be involved. Ocular manifestations, such as an orbital soft tissue mass, mass involving the eyelids or lacrimal gland, uveitis and compressive optic neuropathy have also been reported. Extranodal bone involvement, typically in the metaphysis or diaphysis manifesting as osteolytic or mixed lytic/sclerotic lesion on imaging is seen in 5% to 10% of cases, and it is usually associated with nodal disease. Occasionally, there is involvement of the CNS (intracranial, spinal cord, meninges), lung, heart, gastrointestinal tract, liver, and kidney. Overall prognosis has been found to be correlated to both the number of nodal groups and extranodal systems involved. Significant morbidity and death have been associated with massive tissue invasion of the liver, kidney, lung, brain, and other critical structures.[65]

RDD is more common in children and young adults (median age 20.6 years), though it has also been reported in older adults. RDD arises with increased frequency in children of African descent, with a slight male predominance.

Laboratory evaluation frequently reveals an elevated erythrocyte sedimentation rate (ESR), moderate polyclonal hypergammaglobulinemia, anemia, and granulocytosis. Subtle abnormalities of immune indices may also be seen. Involved lymph nodes (see Fig. 53.2I–L) show marked sinusoidal dilation with proliferation of foamy histiocytes within the sinuses. Eosinophils are usually low in number, but

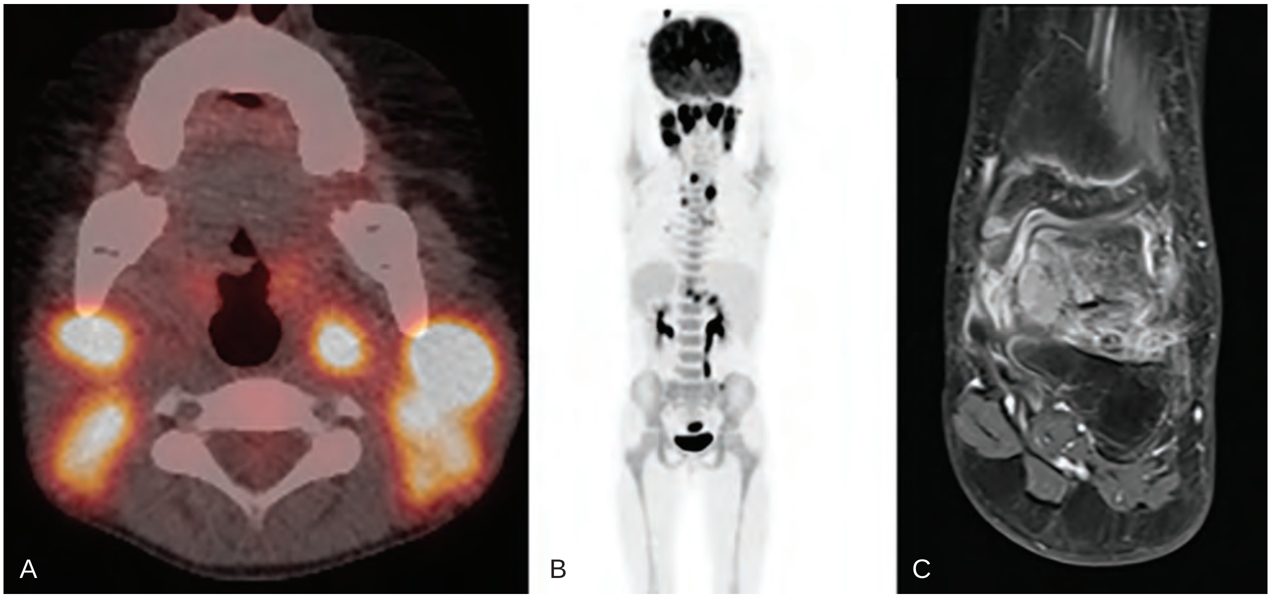

Figure 53.6 ROSAI-DORFMAN DISEASE. (A and B) Typical hypermetabolic cervical lymphadenopathy demonstrated in PET-CT scan; (C) extramedullary talus lesion.

plasma cells are abundant. A characteristic finding, referred to as *emperipolesis*, demonstrates intact leucocytes trafficking through histiocytes as observed best by electron microscopy. The proliferating histiocytes appear to be macrophages. These large, pale cells show variable expression of cytoplasmic and nuclear S100. They can be distinguished from Langerhans cells found in the lymph nodes of patients with classic LCH by CD163+ and CD1a–/CD207– immunohistochemistry.[54]

The etiology of RDD is not well defined and is thought to be variable across the varied phenotypic presentation. Activating MAPK pathway mutations have been reported in RDD lesions, but not with the same frequency as other myeloid neoplastic histiocytic disorders discussed above.[56]

The prognosis of RDD is variable. Overall, the outcomes are usually favorable with disease manifestations that may spontaneously subside over several months to years, especially in the cases of cutaneous and nodal RDD in children. For other patients, the course can be unpredictable with periods of remission and relapse. As the disease resolves, extranodal disease typically regresses before nodal disease. Mortality related to RDD or as a result of direct complication of the disease has been reported to be approximately 10%. No standard of care exists and treatment options vary on a case-to-case basis, depending on the site(s) of disease, associated morbidities, etc. Treatment options range from observation only, corticosteroids, surgical resection, radiotherapy, sirolimus or other immunomodulatory agents, and/or chemotherapy with variable responses and based largely on individual case reports or small case series.[64] Lesions may respond to corticosteroids but typically rebound when steroids are weaned. Case reports and series note potential for responses to vinca alkaloids or low-dose methotrexate/6MP. However, the results with these agents have been inconsistent. Recent reports have nucleoside analogs, especially single-agent clofarabine has the potential to achieve cure in patients with SHML who require systemic therapy. Targeted therapies targeting the MAPK pathway have shown robust activity in histiocytic disorders and are being explored in RDD in patients with proven activating MAPK pathway mutations.[47] Attempts at treatment should generally be reserved for cases with multifocal/extranodal RDD, progressive disease, or special circumstances such as tracheal or epidural compression, invasion of other vital structures, or significant cosmetic disfigurement.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

HLH is a life threatening, hyperinflammatory syndrome that can occur as a familial or sporadic disorder. In the broad classification of histiocytic disorders (see Table 53.1), HLH is categorized as a monocyte/macrophage-related histiocytic disorder. HLH derives its name from its sometimes distinctive pathology (hemophagocytosis), in which macrophages appear to be widely infiltrating tissues and engulfing blood and BM cells in a nonspecific fashion. However, HLH is best conceptualized as an immune regulatory disorder, which is characterized by clinical signs and symptoms of extreme inflammation and the development of cytopenias, hepatitis, and CNS dysfunction, which are severe and life threatening.[66] Indeed, it has been proposed that the name of this disorder should be changed to "hyperinflammatory lymphohistiocytosis" (also HLH).

HLH was first described as a familial disease by Farquhar and Claireux in 1952, which they named "familial hemophagocytic reticulosis." Through the years, the syndrome of HLH has been recognized as both a sporadic and familial disorder and in various clinical contexts. Although we prefer to lump each of these clinical variations into a single syndrome (HLH), the medical literature has used a plethora of names: familial erythrophagocytic lymphohistiocytosis, viral-associated hemophagocytic syndrome, and malignancy-associated hemophagocytic syndrome, among others. Furthermore, macrophage activation syndrome (MAS), the systemic inflammatory syndrome observed in association with rheumatologic disorders, is likely a variant of HLH syndrome because both "classic" HLH and MAS have similar clinical phenotypes and appear to share some underlying mechanisms. The International Histiocyte Society formally adopted the name of HLH in 1998 and defined criteria for its diagnosis, which were updated in 2004 (Table 53.5).[67] Despite clinical and scientific advances, uncertainty remains about how to conceptualize and recognize HLH. Due to the complexity of diagnostic criteria and similarity to other inflammatory disorders, diagnosis is often delayed. Moreover, with increasing awareness, the syndrome misdiagnosis has become a major issue of concern.

TABLE 53.5 **Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis**

A. A molecular diagnosis consistent with HLH: Pathologic mutations of *PRF1*, *UNC13D*, *Munc18-2*, *Rab27a*, *STX11*, *SH2D1A*, or *BIRC4*

-OR-

B. **Five** out of the **eight** criteria listed below are fulfilled:

1. Fever ≥38.3°C
2. Splenomegaly
3. Cytopenias (affecting at least 2 of 3 lineages in the peripheral blood):
   Hemoglobin <9 g/dL (in infants <4 weeks: hemoglobin <10 g/dL)
   Platelets <100 × 10^3/mL
   Neutrophils <1 × 10^3/mL
4. Hypertriglyceridemia (fasting, ≥265 mg/dL) and/or hypofibrinogenemia (≤150 mg/dL)
5. Hemophagocytosis in bone marrow or spleen or lymph nodes or liver
6. Low or absent NK-cell activity
7. Ferritin >500 ng/mL[a]
8. Elevated soluble CD25 (soluble IL-2 receptor alpha)[b]

[a] While the HLH-2004 protocol uses ferritin >500 ng/mL, we generally view ferritin>3000 ng/mL as concerning for HLH, and ferritin >10,000 as highly suspicious.[7]

[b] Elevations above age-adjusted, laboratory-specific normal levels (defined as >2 SD from the mean).

Epidemiology

The true incidence and prevalence of HLH are unknown and remain difficult to ascertain accurately. The diagnosis of HLH is challenging because of its variable presentation and the many nonspecific clinical features it shares with other disease processes. HLH is considered to be rare, but increasing awareness and recognition of the syndrome is leading to more frequent diagnoses. Currently, it is estimated that the autosomal recessive forms of familial HLH have a prevalence of 1 in 50,000 live births. A recent report estimated the incidence of HLH of 1 in 100,000 children, and a review of HLH cases from the largest pediatric hospital in Texas revealed 1 in 3,000 inpatients admissions associated with HLH diagnosis.[68,69] Because of the typically autosomal recessive nature of familial HLH (F-HLH), this disorder is reported to occur more frequently in isolated populations or kindreds with consanguinity. Although HLH was thought to be a primarily pediatric disease, it is diagnosed in all ages, and in a large Japanese cohort, 40% of the patients were adults.[70] The incidence may be as high as 1 in 2000 adult admissions at tertiary centers.[71]

Pathophysiology

HLH is a syndrome of excessive inflammation and tissue destruction due to abnormal immune activation. Different forms of HLH probably share the same terminal pathway though each has a different pathogenic root.

The immunologic basis of F-HLH, the prototype of disease, was long suspected because of its inflammatory nature and the finding of cytotoxic deficiencies and other immune abnormalities in patients with HLH. The first confirmation that HLH is an immunodeficiency came in 1999 with the discovery of perforin mutations in affected patients. However, unlike other immunodeficiencies, the principal clinical characteristic of HLH is one of intense, prolonged systemic inflammation rather than unusual or severe infections. Although this inflammation may be triggered by infection or vaccination, the inflammation itself (and not apparently the sometimes benign or transient infection) appears to drive the clinical features of HLH. Thus, F-HLH appears to be a deficiency of immune regulation. Animal studies have detailed how this immune regulation functions and how deficiencies may lead to HLH. In brief, cytotoxic lymphocytes kill not only infected cells but also antigen-presenting cells (APCs). These APCs promote T-cell activation during infection. This persistence of activating signals leads to excessive or prolonged acute T-cell activation. Abnormal T-cell activation, in turn, leads to the activation of macrophages and the development of disease pathology. In animal models, IFN-γ appears to be the critical nexus between T-cell activation and disease development.[72] Furthermore, clinical testing of antibodies against IFN-γ (emapalumab) has proven IFN-γ is a key driver of the disease.[73] An underlying lesion of immune regulation and the associated pathophysiology is less clear in apparently sporadic cases of HLH. These cases were historically referred to as *secondary HLH*. However, the traditional dichotomy between primary (familial) HLH and secondary HLH (associated with infections, malignancy, or autoimmunity) is becoming increasingly murky.[74] Further obscuring this dichotomy, a recent report by Zhang et al. described a large series of adults with HLH who were found to have genetic mutations typically seen in children with familial HLH.[75]

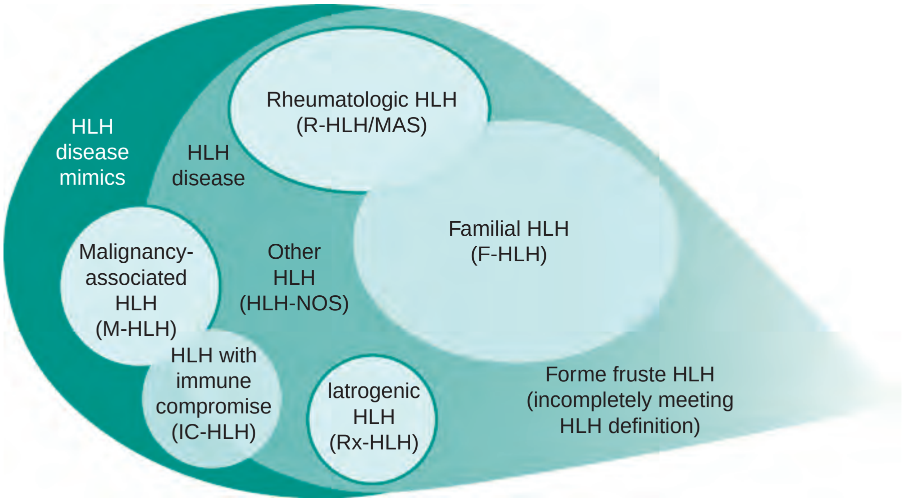
Recently, the North American Consortium for Histiocytosis (NACHO) has defined the following terminology to help differentiate the different clinical scenarios answering the diagnostic criteria (Fig. 53.7)[76]:

1. HLH syndrome: A condition that describes patients displaying sufficient diagnostic features (from the HLH-2004 diagnostic criteria presented in Table 53.5) to fulfill the pattern of HLH.
2. HLH disease: A condition characterized by distinct immune dysregulation in patients who are likely to benefit from immunosuppression. Only a subset of patients with "HLH syndrome" have "HLH disease."
3. HLH disease mimics: Disorders leading to the HLH pattern but which are not likely to benefit from immune suppression should be viewed as "disease mimics."

HLH may present in a variety of clinical contexts and with a variety of etiologic associations. Patients with F-HLH are those with clear familial inheritance or known genetic causes, are usually infants or younger children, and are thought to have fixed defects of cytotoxic function (although this is not always the case). These patients have a clear risk of HLH recurrence and will generally not survive long term without hematopoietic cell transplantation (HCT). Although HLH in these patients can be associated with infections (e.g., cytomegalovirus [CMV] or Epstein-Barr virus [EBV]) or vaccination, the immunologic trigger is often not apparent.

However, some of the patients with HLH disease are older children (or adults) who present without a family history or known genetic cause for their HLH. These patients typically have concurrent infections or medical conditions that appear to trigger their HLH, such as EBV infection, malignancy, or rheumatologic disorders. The list of triggering stimuli for both familial and apparently nonfamilial HLH is extensive. Patients with nonfamilial HLH are sometimes reported as having immune studies, including NK cell function, that normalize with disease resolution, although in the authors' experience this is variable or unclear. Although the mortality rate from HLH may be significant, the risk of recurrence in cases of secondary HLH is poorly defined. Recurrence of HLH in the absence of autoimmune disease or malignancy is generally considered to be good evidence that a patient has F-HLH, regardless of the other clinical features. In the absence of a known genetic defect or family history, it is often not possible to make an initial diagnosis of F-HLH.

A variety of genetic causes of F-HLH have been identified, all either autosomal recessive or X-linked (Table 53.6). Most of these



HLH disease mimics
HLH disease
Rheumatologic HLH (R-HLH/MAS)
Familial HLH (F-HLH)
Malignancy-associated HLH (M-HLH)
Other HLH (HLH-NOS)
HLH with immune compromise (IC-HLH)
Iatrogenic HLH (Rx-HLH)
Forme fruste HLH (incompletely meeting HLH definition)

Figure 53.7 CATEGORIZING HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH). The HLH syndrome includes all conditions meeting consensus diagnostic criteria. This syndrome includes conditions that would benefit from HLH-directed immunosuppressive therapies, which are termed "HLH disease," and those conditions that would not benefit from such therapy or require entirely different treatments, termed "HLH disease mimics." HLH disease includes recognizable subgroups: familial HLH with clear genetic etiology, HLH associated with malignancy, HLH associated with rheumatologic conditions (also called MAS), HLH observed after immune-activating therapies (iatrogenic HLH, also called cytokine release syndrome), HLH associated with immune compromise (either primary immune deficiency or treatment-related immune suppression), and HLH not associated with other specific conditions. Recognition of these subcategories is valuable as this may alter treatment, though some categories overlap with each other or have indistinct borders (as indicated above) and may include examples of both HLH disease and HLH disease mimics. Use of these category-specific terms is preferred over the historical terms of "primary" and "secondary" because the older concepts are ambiguous due to increasing understanding of genetic complexity, involvement of infection in triggering multiple distinct variations of HLH, and varied application. Incomplete, forme fruste episodes of HLH (similar, but not completely fulfilling diagnostic criteria) are also well recognized in patients with familial HLH and may occur in others, such as "mild MAS" in soJIA patients. *(Adapted from Jordan MB, Allen CE, Greenberg J, et al. FHL, Familial HLH; *HLH*, hemophagocytic lymphohistiocytosis.

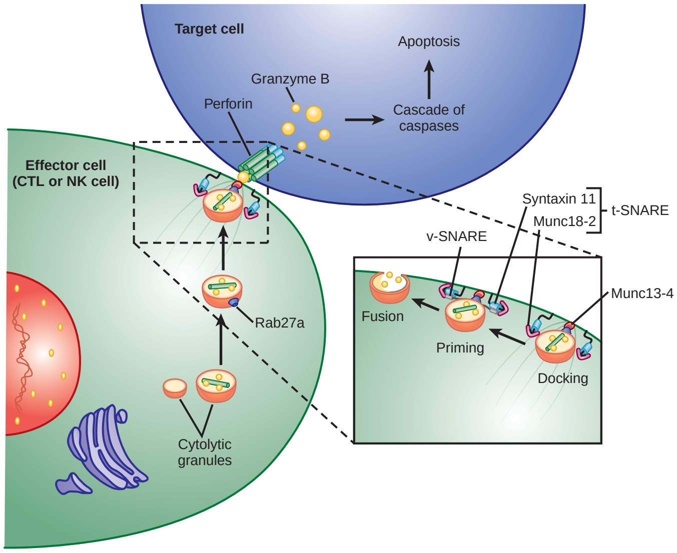

Figure 53.8 MECHANICS OF CYTOTOXIC FUNCTION REVEALED BY HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH)–ASSOCIATED GENE MUTATIONS. Hemophagocytic lymphohistiocytosis-associated genetic abnormalities (in the indicated genes) may affect granule-dependent lymphocyte cytotoxicity by impairing trafficking, docking, priming for exocytosis, or membrane fusion of cytolytic granules. The function of this pathway may also be severely impaired by loss of functional perforin, the key delivery molecule for proapoptotic granzymes. Diverse mutations in this pathway all give rise to similar clinical phenotypes (albeit of variable severity). *LYST* (the gene affected in Chediak-Higashi syndrome) is not portrayed because its function is not entirely clear, although it appears to play an important role in the maintenance of normally sized (and functional) cytolytic granules. *CTL*, Cytotoxic T lymphocyte; *NK*, natural killer, *SNARE*, soluble *N*-ethylmaleimide-sensitive fusion attachment receptor protein. *(Adapted from Jordan MB, Allen CE, Weitzman S, et al. How I treat hemophagocytic lymphohistiocytosis. Blood. 2011;118:4041–4052.)*

genetic lesions affect a biologic pathway referred to as *granule-dependent*, or *perforin-dependent, cytotoxicity* (Fig. 53.8).[66] This pathway is used by T cells and NK cells to kill target cells, typically those infected by viruses. When triggered, specialized lysosomal granules containing perforin, granzymes, and other proteins are released, leading to apoptotic death of target cells. The first genetic lesions identified in patients with HLH were mutations in *prf1*, the gene encoding the protein perforin. *Prf1* mutations account for about 15% to 20% of HLH in certain geographic areas and are known as familial HLH 2 (FHL2). FHL2 has mild and severe phenotypes that correlate with the degree of mature perforin protein that is produced. Abnormalities of granule formation, mobilization, and extrusion are also identified as causes of HLH. Munc13-4, a protein essential to the exocytotic process, is mutated in FHL3. FHL3 has a worldwide distribution and accounts for 15% to 20% of all hereditable HLH. However, recent discoveries of previously unappreciated intronic mutations in this gene may expand the proportion of patients with FHL3. FHL4 is caused by mutations in the protein syntaxin 11, a member of the soluble *N*-ethylmaleimide-sensitive fusion attachment receptor protein family of proteins, which is necessary for the fusion of cytotoxic vesicles with the plasma membrane to release their granules. Mutations in the syntaxin-binding protein 2, also important for this process, have been designated FHL5. The genetic defect responsible for FHL1 has not been identified, and no mutations in granzyme proteins have been associated with HLH.

Two X-linked causes of HLH are known. The first, called "X-linked lymphoproliferative syndrome 1" (or XLP1), is caused by defects in SH2D1A or SAP (signaling-lymphocytic-activation-molecule-associated protein). This disorder is a complex one characterized by lymphoproliferation, hypogammaglobulinemia, excess risk of lymphoma, and development of HLH. It appears to share some of the pathophysiology with classic familial HLH, although other abnormalities (of B cells and other cells) make this disorder distinctive. The second X-linked cause of HLH, sometimes called "XLP2" (although this is disputed), is abnormalities of a gene/protein called baculoviral inhibitor of apoptosis protein repeat-containing protein 4 (BIRC4)/X-linked inhibitor of apoptosis protein (XIAP). The apparently unique pathophysiology of HLH caused by XIAP deficiency is not understood. Other immunodeficiency syndromes caused by defects in lysosomal trafficking have been linked to life-threatening episodes of HLH. These include Chediak-Higashi syndrome, Griscelli syndrome, and Hermansky-Pudlak syndrome, type II.

Taken together, all the genetic disorders described previously still account for fewer than half of the diagnosed cases of HLH in children, including many familial cases still awaiting molecular definition. Until recently, it was widely believed that symptoms of HLH triggered by genetic causes arose during infancy and early childhood. With the more widespread availability of genetic testing, it is apparent that the first significant episode of HLH can occur throughout life from prenatal presentations through the seventh decade of life. Distinctions between primary (genetically determined) and secondary (acquired) forms of HLH become increasingly blurred together as new genetic causes are identified and patients who develop HLH beyond early childhood or in the contexts of EBV infection or autoimmune disease are being found to share some of the same genetic etiologies.

Diagnosis

Because of the severe nature of this disorder and the existence of disease-altering therapies, it is crucial to identify patients early in their course.

The Histiocyte Society established diagnostic criteria for the HLH-2004 trial, which is widely used for patients not treated in this trial, using both clinical and laboratory findings (see Table 53.5). Although imperfect, these criteria are widely accepted for the diagnosis of HLH.

Laboratory verification of a known genetic defect confirms the diagnosis independent of the presence or absence of any clinical signs or symptoms. However, genetic diagnosis is not usually available in a timely fashion for patients with acute clinical presentations. In the absence of a genetic diagnosis, five of the eight clinical criteria must be met to make a diagnosis. It is important to note that NK cell dysfunction is only present in about 50% of patients with HLH. Additionally, hemophagocytosis may not be present early in the HLH disease process. The HLH-probability score (HScore) was developed as a diagnostic tool for reactive HLH in adults.[77]

Initial symptoms of HLH are nonspecific and may overlap with other inflammatory or hematopoietic diseases. No single sign or symptom has sensitivity and specificity to allow an unambiguous HLH diagnosis. Close clinical observation with repeated laboratory assessments are mandatory for diagnosis. Thus, conditions fulfilling this syndromic definition may be conceptually split into *HLH disease* (F-HLH and others) and *mimickers* of HLH disease. Fig. 53.9 displays a practical algorithm from the NACHO consortium to aid clinicians make a timely diagnosis while excluding "HLH mimics." Why is this concept important? HLH typically requires prompt recognition and treatment, often before all data can be gathered. However, this aggressive stance should be balanced by a cautious and careful exclusion of conditions that look like HLH but would not benefit from or even be harmed by immune suppression and may require different treatments. HLH triggers/activators should be persistently sought, despite ongoing HLH treatment. Undiagnosed malignancy is especially problematic as HLH-directed therapy often obscures diagnosis. Moreover, the cases should be divided by the HLH activator because each has its characteristics and treatment. Specific etiologies for HLH are discussed at the end of this chapter.

*These studies are helpful because they may rapidly confirm a clinical diagnosis by defining a potential immune/genetic etiology for HLH
**These studies may help eliminate other conditions in the differential diagnosis and/or define treatable underlying triggers for HLH

Figure 53.9 THE DIAGNOSTIC ALGORITHM FOR HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS. *(Adapted from Jordan MB, Allen CE, Greenberg J, et al. Challenges in the diagnosis of hemophagocytic lymphohistiocytosis: recommendations from the North American Consortium for Histiocytosis (NACHO). 2019. Pediatr Blood Cancer. 2019;66(11):e27929.)*

Clinical Manifestations

The classic presentation of HLH consists of prolonged, hectic fevers (usually present for 1 to 2 weeks before diagnosis), hepatosplenomegaly, and cytopenias. Neurologic symptoms are common and distinctive features of these patients; However, HLH may present in many forms, including fever of unknown origin (FUO); hepatitis or acute liver failure; and sepsis-like, Kawasaki-like, and primary neurologic abnormalities. Not all of the HLH diagnostic criteria may be present initially, so it is important to follow clinical signs and laboratory markers of pathologic inflammation repeatedly to identify the trends. Typical clinical features seen in patients with HLH, grouped by organ system, are described in the following text.

Prolonged Fever

FUO is a very common diagnosis in general pediatric wards, and differentiating HLH from other causes of FUO may be challenging. In one series, patients ultimately diagnosed with HLH presented with fevers above 102°F (38.8°C) for a median of 19 days (range: 4 to 41 days). In patients with FUO, cytopenias, highly elevated ferritin (>3000 g/dL), or sCD25 significantly above age-adjusted normal ranges generally suggest that a complete HLH diagnostic evaluation should be pursued.

Liver Disease and Coagulopathy

Most patients with HLH have variable evidence of hepatitis at presentation. HLH should be considered in the differential diagnosis of acute liver failure, especially if lymphocytic infiltrates are noted on biopsy. Autopsy evaluation of the liver has shown chronic persistent hepatitis with periportal lymphocytic infiltration in the majority of patients. Neonates with HLH may present with hydrops fetalis and liver failure. Most patients have evidence of disseminated intravascular coagulation (DIC) and are at high risk for acute bleeding. Furthermore, patients with HLH caused by degranulation defects may have intrinsic platelet dysfunction.

Bone Marrow Failure

Anemia and thrombocytopenia occur in more than 80% of patients at the time of presentation with HLH. The cellularity of BM aspirates varies from normocellular to hypocellular or hypercellular. The prevalence of hemophagocytosis in association with HLH diagnosis ranges from 25% to 100%. Although hemophagocytosis in BM is associated with HLH, the morphologic phenomenon may also be induced by more common events, including blood transfusions, infection, autoimmune disease, and other forms of BM failure or causes of red blood cell destruction. Despite the nomenclature of HLH, diagnosis of HLH should never be made or excluded solely on the presence or absence of hemophagocytosis. Infiltration of BM or liver by CD163$^+$ macrophages, along with global clinical evaluation, may distinguish HLH from other causes of hemophagocytosis.

Skin Manifestations

Patients may have a variety of skin manifestations, including generalized maculopapular erythematous rashes, generalized erythroderma, edema, panniculitis, inflamed papular lesions, petechiae, and purpura. The incidence of skin manifestations ranges from 6% to 65% in published series with highly pleomorphic presentations. Some patients may present with features suggestive of Kawasaki disease, including erythematous rashes, conjunctivitis, red lips, and enlarged cervical lymph nodes. Rashes may correlate with lymphocyte infiltration on skin biopsy, and hemophagocytosis may also be found.

Pulmonary Dysfunction

Patients may develop pulmonary dysfunction that leads to urgent admission to the intensive care unit. In a review of the radiographic abnormalities in 25 patients, 17 had acute respiratory failure with alveolar or interstitial opacities, with fatal outcomes in 88% of those cases.

Brain, Ophthalmic, and Neuromuscular Symptoms

More than one-third of patients present with neurologic symptoms, including seizures, meningismus, decreased level of consciousness, cranial nerve palsy, psychomotor retardation, ataxia, irritability, or hypotonia. The cerebrospinal fluid (CSF) is abnormal in more than 50% of HLH patients with findings of pleocytosis, elevated protein, or hemophagocytosis. MRI findings are highly variable and include discrete lesions, leptomeningeal enhancement, or global edema, and images correlate with neurologic symptoms. Retinal hemorrhages, swelling of the optic nerve, and infiltration of the choroid have been reported in infants with HLH. Diffuse peripheral neuropathy with pain and weakness secondary to myelin destruction by macrophages may also occur.

Laboratory Manifestations

Laboratory manifestations are a critical component of diagnosing HLH. Biochemical abnormalities noted on clinical laboratory assessment include anemia, thrombocytopenia, neutropenia, elevated liver transaminases, hyperbilirubinemia, hypofibrinogenemia, coagulation abnormalities, hypoalbuminemia, hyponatremia, hypertriglyceridemia, elevated soluble CD163, elevated soluble CD25 (sCD25; also called "soluble IL-2 receptor"), and hyperferritinemia. Specialized immunologic testing may reveal low or absent NK cell or cytotoxic T lymphocyte function (although this is not always seen), low levels of perforin or other disease-associated proteins (e.g., SAP or XIAP), and decreased degranulation (observed with mutations affecting granule trafficking). Additionally, pathologic examination of BM biopsy, liver biopsy, CSF, spleen or lymph node, or even occasionally peripheral blood may reveal hemophagocytosis and infiltration with CD163$^+$ macrophages and activated T cells (see Fig. 53.2M–Q). Examination of CSF reveals pleocytosis, elevated protein, and elevated neopterin levels with CNS involvement. Brain MRI often reveals polymorphic white or grey matter abnormalities in such cases.

Elevations in sCD25 are a particularly useful and notable laboratory feature of HLH. In the authors' experience, this marker is dynamically associated with "active" HLH, and patients with active HLH rarely, if ever, have normal levels of sCD25. Of note, the interpretation of soluble IL-2 receptor levels must be undertaken with care because normal levels change with age and the method of analysis. Despite a few small reports of increased soluble IL-2 receptor levels in sepsis and hematologic malignancies, significant elevations of this marker are rarely observed outside the context of HLH. However, the clinical utility of sCD25 is often compromised by delays because most institutions must send patient samples to referral laboratories. Similarly, though not as well established, because HLH appears to be primarily driven by IFN-γ, elevations of CXCL9 (a sensitive indicator of IFN-γ bioactivity) should be seen in untreated cases of HLH disease. Because of its ready availability in most hospitals, the serum ferritin level can serve as an important adjunct to the decision-making process. The HLH diagnostic guidelines define a cutoff at greater than 500 μg/L, which may be observed in sepsis or other hyperinflammatory conditions. Ferritin levels in HLH are usually dramatically higher, with some series finding mean levels near 45,000 μg/L. A review of elevated ferritin values at a large pediatric academic tertiary care hospital demonstrated that a ferritin level greater than 10,000 was 90% sensitive and 96% specific for HLH.

While specialized immunologic testing may facilitate diagnosis, if a diagnosis can be made without them, then treatment should not be delayed pending these results. Likewise, treatment should not be delayed for assessment of CNS involvement, though this should always be conducted (once a lumbar puncture may be safely performed).

Differential Diagnosis of Hemophagocytic Lymphohistiocytosis

Because HLH presents as an inflammatory syndrome, the differential diagnosis of this disorder is a broad one. Infection must be considered as either a mimic of HLH or as an underlying trigger of the disorder. The list of infections reported as associated with HLH is extensive. If the patient presents with acute multiorgan failure, then sepsis is generally considered first before a diagnosis of HLH is considered. Viral infections, including EBV, CMV, dengue, and severe influenza, should always be considered and treated. Protozoan infections, including malaria, toxoplasmosis, and leishmaniasis, may be a consideration in endemic areas. Visceral leishmaniasis, in particular, may be clinically indistinguishable from primary HLH. In addition to infectious disorders, rheumatologic disorders, including systemic onset juvenile idiopathic arthritis (soJIA) and Kawasaki syndrome, should be considered. Drug reactions such as Drug Rash with Eosinophilia and Systemic Symptoms (DRESS) syndrome may present as HLH as both a trigger and mimic as treatment requires both withdrawal of the offending agent and prolonged corticosteroids.

Storage diseases including Gaucher disease can mimic HLH (e.g., splenomegaly, cytopenias).

Finally, as either a mimic or trigger, malignancy should be considered, particularly lymphoma and leukemia.

Therapy

Without therapy, survival of patients with active F-HLH is historically reported to be approximately 2 months. Often, the principal challenge for treating patients with HLH is making a timely and accurate diagnosis. Rapid treatment of HLH is essential, especially for those who are acutely ill or clinically deteriorating. Currently, the standard of care for HLH should be considered to be treatment with etoposide and dexamethasone, the HLH-94 protocol, as illustrated in Fig. 53.10. The protocol is based on an 8-week induction therapy with dexamethasone, etoposide, and intrathecal methotrexate. The principal goal of induction therapy is to suppress the life-threatening inflammatory process that underlies HLH. At the end of 8 weeks, patients are either weaned off therapy or transitioned to continuation therapy, which is intended only as a bridge to transplantation. HLH-94 treatment components are highly effective in treating hyper inflammation in adults with HLH. However, due to the heterogeneity of HLH disease in adults, the protocol is not suitable for all patients. Each adult with HLH should be treated based on the trigger/activator as discussed at the end of this chapter.

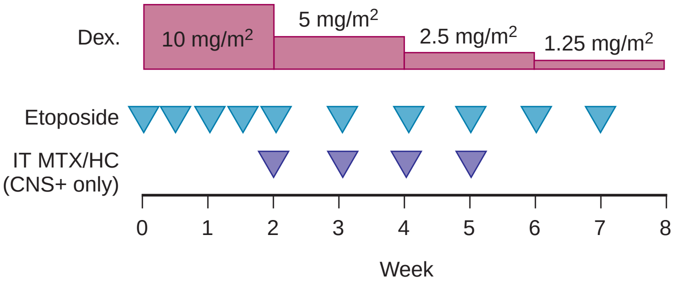

Figure 53.10 INDUCTION THERAPY FOR HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH). Based on the HLH-94 study, this approach should be considered standard of care for all patients not enrolled in clinical trials based on published evidence of efficacy. Etoposide is dosed as 150 mg/m^2 per dose. Alternatively, for patients weighing less than 10 kg, consideration may be given to dosing etoposide as 5 mg/kg per dose. Dexamethasone *(Dex.)* is dosed as indicated and may be given orally or intravenously, although the latter is preferred at therapy initiation. IT MTX/HC should be given to patients with evidence of CNS involvement as early as lumbar puncture may be safely performed (which may vary from the diagram) and dosed as follows: age younger than 1 year, 6/8 mg *(MTX/HC)*; age 1 to 2 years, 8/10 mg; age 2 to 3 years, 10/12 mg; and age older than 3 years, 12/15 mg. Weekly intrathecal therapy is generally continued until at least 1 week after resolution of CNS involvement (both clinical and cerebrospinal fluid indices). *CNS*, Central nervous system; *IT MTX/HC*, intrathecal methotrexate and hydrocortisone. *(Adapted from Jordan MB, Allen CE, Weitzman S, et al. How I treat hemophagocytic lymphohistiocytosis. Blood. 2011;118:4041–4052.)*

It is critical to search for and treat underlying triggers of HLH and institute specific antimicrobial therapy. Rituximab is often helpful in controlling EBV infection. Intravenous immunoglobulin (IVIG) is an appropriate adjunct for most viral infections. If the patient is stable and not severely ill, consideration can be given to treating the underlying trigger with disease-specific therapy with or without corticosteroids and close follow-up. However, in most cases, an aggressive therapeutic approach is warranted and may reasonably be initiated before obtaining final results for all diagnostic studies. Specifically, HLH therapy should not be withheld while awaiting results of genetic testing because our understanding of HLH-associated gene defects remains incomplete and testing typically takes weeks to complete. With the exception of autoimmune disease and malignancy, initial therapy for patients with suspected familial or reactive HLH does not differ.

Induction Therapy

The current standard of care consists of a decrescendo course of etoposide and dexamethasone with or without intrathecal therapy (see Fig. 53.10). Ideally, critically ill patients should be treated at facilities familiar with care of cancer and BMT patients. It is important to initiate therapy promptly even in the face of unresolved infections, cytopenias, or organ dysfunction. After starting therapy, patients should be monitored closely for signs of improvement as well as potential complications and toxicities, and therapy may need to be customized. Adult patients and especially the elderly ones may have comorbidities, making them more vulnerable to the toxicities of etoposide. A reduced etoposide frequency, from twice weekly to once a week, with or without a reduction on dose from 150 mg/m^2 to 50 to 100 mg/m^2 should be considered.[78] In the HLH-2004 study, cyclosporine was administered upfront instead of after 8 weeks, as in HLH-94, and pre-HCT mortality was slightly reduced. Because the improvement was not significant and does not justify the toxicities of the treatment, HLH-94 remains the recommended standard of care. For patients who respond well, with a resolution of symptoms and normalization of inflammatory markers, therapy may be weaned per protocol. However, dexamethasone doses and etoposide frequency may need to be increased in response to disease reactivation (see the Salvage Therapy section). Deterioration of liver function and blood counts as well as steady increases in serum ferritin, sCD25, and sCD163 tests may signal relapse of HLH disease activity. If patients do not display at least a partial response within 2 to 3 weeks of therapy initiation, salvage therapy should be considered. Recurrence of fever and increased inflammatory markers after an apparent response should also prompt a careful search for opportunistic infection. Most non-F-HLH adult patients may continue the full course of induction (8 weeks) if no major toxicity is limiting the treatment. However, many patients require less than 8 weeks.

Central Nervous System Disease

Patients may present with CNS involvement or may have recurrent disease as treatment doses are being tapered. All patients should receive a careful neurologic examination, lumbar puncture, and brain MRI, even if they are asymptomatic, as soon as they can be safely performed. Changes in mental status at any time during therapy should be investigated urgently. Patients with proven CNS involvement should be treated with weekly intrathecal methotrexate and hydrocortisone until CSF abnormalities and symptoms normalize. The risk of posterior reversible encephalopathy syndrome (PRES) appears to be significant during induction therapy. Although the etiology of PRES is incompletely understood, it is more frequent in settings of hypertension and is also associated with cyclosporine use. Blood pressure should be aggressively managed during induction. Because CNS involvement suggests a familial etiology and because this disease feature is associated with substantial risks for long-term morbidity, HCT should be considered for patients with this complication.

Supportive Care

Supportive care guidelines for patients on therapy for HLH should be similar to standard practice for patients undergoing HCT, including acute care nursing, *Pneumocystis jiroveci* prophylaxis, fungal prophylaxis, IVIG supplementation, and neutropenic precautions. Any new fever should be evaluated for HLH reactivation, as well as opportunistic infection, and empiric broad-spectrum antibiotic therapy should be initiated. Because of inflammation, consumptive coagulopathy, and intrinsic platelet defects in some patients, they are at a very high risk of spontaneous bleeding. The authors aim to maintain platelet count greater than 50×10^9/L and do not recommend prophylactic heparin, which is sometimes used in acutely ill patients. Platelets, fresh-frozen plasma, cryoprecipitate, and occasionally activated factor VII are required for acute bleeding.

Continuation Therapy

Patients who can be weaned off of dexamethasone and etoposide without recurrence, recover normal immune function, and have no identified HLH-associated gene defects may stop therapy after the 8-week induction course. HCT is generally recommended in patients with age younger than 2 years, CNS involvement, recurrent or refractory disease, persistent NK cell dysfunction, or proven familial or genetic disease. Continuation according to HLH-94 consists of pulses of dexamethasone and etoposide (etoposide,150 mg/m^2 every 2 weeks alternating with dexamethasone 10 mg/m^2/day for 3 days every 2 weeks). Cyclosporine may be added in patients with stable blood pressure and adequate liver and kidney function. Patients on continuation therapy should proceed to HCT as quickly as possible because of the ongoing risks of infection, disease reactivation, or leukemia or myelodysplastic syndrome related to prolonged use of etoposide.

Salvage or Second-Line Therapy

A significant number of patients with HLH either fail to respond adequately to current therapies or relapse before HCT. Approximately 50% of patients treated in the HLH-94 study experienced a complete resolution of HLH, 30% experienced a partial resolution, and approximately 20% died before HCT. Notably, most deaths occurred during the first few weeks of treatment and may reflect either preexisting morbidities or primary refractory disease. Although it is hoped that some patients will fare better with more prompt diagnosis of HLH, others remain unresponsive to standard therapy. Emapalumab, an IFN-γ blocking monoclonal antibody, was recently approved by the US Food and Drug administration for refractory or recurrent HLH after a successful clinical trial.[73] Alemtuzumab, anti-CD52, was reported to have significant activity against refractory HLH in a retrospective series of patients and can be used as a bridge for HCT. Although refractory HLH appears to have a dismal prognosis, approximately 70% of patients in this series survived. Because of its immunoablative qualities, alemtuzumab should be used with caution and by those with experience caring for profoundly immune-compromised patients. CMV reactivation and adenoviremia were frequent complications of this therapy. In contrast to refractory patients, those patients who initially respond well to standard therapy but then relapse as treatment is tapered or withdrawn often respond to the reintensification of therapy with standard agents. Because of the variability in patient responses, a critical aspect of initial or salvage therapy is close monitoring of the patients for improvement and potential toxicities such as BM suppression or infection.

Hematopoietic Cell Transplantation

Transplantation is performed to prevent potentially fatal HLH disease recurrence. Because the time to transplant is a factor in morbidity and mortality from the disease, a donor search should begin at the time of diagnosis even though the precise etiology of HLH (e.g., genetic defect) has not yet been defined. Generally, HCT is recommended in cases of documented familial HLH, recurrent or progressive disease despite intensive therapy, and CNS involvement. Moreover, patients with a hematologic malignancy that cannot be cured with conventional agents (but may be treated with HCT) should also proceed to transplant.[79] Long-term disease-free survival after HCT was approximately 50% to 65% before the year 2000, regardless of whether a matched sibling or closely matched unrelated donor was used. Most patients transplanted during that era succumbed to “transplant-related” complications during the first 100 days after infusion. A significant proportion of fatal complications involved inflammatory conditions termed *acute respiratory distress syndrome*, *veno-occlusive disease*, and *multisystem organ failure*, *unspecified*. In rare cases, residual HLH was identified at autopsy despite the use of myeloablative conditioning therapy.

During the past decade, the use of reduced-intensity conditioning (RIC) regimens before HCT has been investigated after encouraging results from an institutional series.[80,81] Most cases of RIC pretreatment have included alemtuzumab and demonstrated superior early post-transplant survival. In a single-center analysis directly comparing HCT outcomes after myeloablative conditioning versus RIC, a statistically significant improvement was observed after RIC conditioning, with all patients surviving at 6 months after transplant. Published data regarding outcome of RIC transplants using umbilical cord blood are not sufficient to draw conclusions regarding safety or efficacy. A retrospective European study did not show superiority of RIC over myeloablative conditioning (MAC) in adults. Donor choice should also take into account the possibility of an occult predisposition to HLH in siblings of patients without identified gene defects. Much remains to be learned and refined regarding the optimal application of alemtuzumab as well as other agents used before HCT. The timing of pretransplant alemtuzumab impacts the probability of graft-versus-host disease, mixed chimerism, and, in rare cases, rejection. Other factors, such as donor source, human leukocyte antigen match, cell dose, and patient condition with regard to HLH disease activity at the time of conditioning may all play roles in determining the likelihood of success after RIC HCT. The pretransplant conditioning regimen in malignancy-associated HLH may be guided by disease-specific protocols.

Patients with CNS HLH need close post-transplant follow-up. The authors recommend examination of CSF within 100 days of HCT even in asymptomatic patients. Follow-up MRIs are recommended if pretransplant abnormalities were present. In some patients with mixed or full hematopoietic donor chimerism, HLH disease activity in the CSF can be effectively treated with intrathecal therapy during the early post-transplant months. CNS disease is subsequently controlled as donor immune reconstitution progresses.

Prognosis

Significant strides have been made in the treatment of HLH, with survival now generally ranging from 50% to 70%. In children with nonfamilial HLH, overall survival has been reported at 72%, but only 20% of the patients did not require HCT. Survival is increased in children, irrespective of genetic status, who receive HSCT from matched rather than unmatched donors. RIC pretransplant regimens appear to further decrease mortality. The best outcomes in HSCT are seen in children who have a rapid and complete response to pretransplant

TABLE 53.7 **Distinctive Clinical Contexts in Which Hemophagocytic Lymphohistiocytosis May Arise**

F-HLH	M-HLH	R-HLH	Rx-HLH	IC-HLH
Defects in granule-mediated cytotoxicity	Malignancy triggered HLH	R-HLH triggered by soJIA	Cytokine storm associated with CAR-T-cell therapy	**Primary**[a]

therapies and who do not exhibit significant neurologic involvement. Prompt initiation of HSCT in familial patients after disease remission is obtained is also likely to increase survival. Patients with significant neurologic involvement may experience severe and permanent sequelae even if they survive.

DISTINCTIVE CLINICAL CONTEXTS

HLH, especially in adults can arise in different clinical contexts, summarized in Table 53.7.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS ASSOCIATED WITH MALIGNANCIES

Malignancy may present with HLH at all ages (including infancy), but is increasingly likely at older ages, and is associated with the majority of cases in adults. About 40% to 70% of HLH cases in adults are malignancy-associated (M-HLH). The association of HLH with malignancy has been recognized for decades. Patients may present with the clinical syndrome of HLH associated with undiagnosed underlying malignancy or transformation of an indolent hematologic malignancy, or they may develop HLH during treatment for known malignancy, usually in the context of infection.[82] The pathophysiology of HLH associated with malignancies is not well defined, and the tumor itself may “mimic” the HLH diagnostic criteria. However, the prognosis of these patients is abysmal and the overall survival of patients can be as low as 10% to 20% 5 years overall survival. Lymphoma deserves special mention as it is the most common malignancy associated with HLH at its initial presentation.

Diagnosis and Treatment

Because of the difficulty of distinguishing lymphoma from F-HLH or R-HLH, thorough history and imaging, adults with unexplained HLH should have a thorough evaluation for lymphoma. sCD25 may be disproportionately elevated compared to other features of HLH in patients with occult lymphoma. A ratio of Scd25/ferritin that is >2 strongly supports the presence of lymphoma in the context of HLH syndrome. A tissue biopsy, often guided by PET-CT, should be pursued or at least considered before starting corticosteroids and other therapies that may obscure diagnosis. In patients with HLH of unknown etiology and splenomegaly, splenectomy may be considered to detect lymphomas hiding in the spleen. Treatment of M-HLH should balance HLH-specific and tumor-specific therapy. Corticosteroids are commonly used as a first-line treatment to combat inflammation. In highly active HLH, etoposide (50 to 100 mg/m^2) may be added prior to tumor-specific treatment. Etoposide may be added to CHOP or CHOP-like protocols (cyclophosphamide, doxorubicin, vincristine, etoposide, prednisone) or dose-adapted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin [DA-EPOCH]). Patients in remission who are eligible for treatment intensification may be candidates for autologous SCT, using high-dose etoposide-containing high-dose chemotherapy as primary consolidation. In patients with a malignancy that can only be cured with allogeneic HCT, early HLA phenotyping and decision-making regarding transplant should be made in a timely manner.[83]

When considering M-HLH, it is essential to note that the presence of EBV viremia does not rule out malignancy (including B or T cell lymphomas). On the contrary, EBV by itself can signify the presence of a lymphoproliferative disorder. A weekly treatment with rituximab should be administered (375 mg/m^2 once weekly for 2 to 4 times or until PCR level goes down to 0). If the PCR levels increase with a worsening of HLH signs and symptoms, attempts should be made to identify the affected cell lineage (by sorted PCR of peripheral blood mononuclear cells/ BM biopsy). Patients from Asian and Hispanic countries tend to develop lymphoproliferative disease. These patients should be considered as having EBV lymphoproliferative disorder (EBV-LPD). The treatment of EBV-LPD should start with HLH therapy, followed by CHOP chemotherapy (cyclophosphamide, hydroxydaunorubicin, vincristine, and prednisone) and plan for HCT. Recent reports have shown an impressive response of HLH associated with EBV-LPD to nivolumab (PD-1 checkpoint inhibitors).

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS IN THE CONTEXT OF A RHEUMATOLOGIC DISEASE (R-HLH)

MAS is the name commonly given to a severe, potentially fatal inflammatory condition seen in the context of rheumatologic disorders such as soJIA or systemic lupus erythematosus (SLE). The syndrome of MAS shares many similarities with classic HLH, and many investigators view it as a special form of HLH, suggesting that the name may be changed to rheumatologic HLH (or R-HLH). The main manifestations of MAS include fever, hepatosplenomegaly, lymphadenopathy, severe cytopenias, serious liver disease, and coagulopathy consistent with DIC. Hemophagocytosis is often (although not always) seen in the BM of patients with MAS.

The true incidence of MAS may be underestimated because relatively mild cases of MAS often remained unrecognized. Recent evidence suggests that mild subclinical MAS occurs in as many as one-third of patients with active soJIA and may be the first manifestation of soJIA. Infections or change in medications may precede the diagnosis of MAS. However, in most patients, MAS is triggered by a flare-up of the underlying rheumatologic disease.[84] Published observations suggest that as in HLH, MAS patients have profoundly depressed NK cell function[85] sometimes associated with abnormal perforin expression, and these abnormalities are associated with specific perforin and Munc13-4 polymorphisms.

Diagnosis and Treatment
